

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + Refrain from automated querying Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at http://books.google.com/

ON RATIONAL QUADRATIC TRANSFORMA-TIONS.

BY M. W. HASKELL, PH. D.,

Associate Professor of Mathematics, University of California.

In my inaugural dissertation1 certain quadratic transformations played an important part. Their generation by the combination of conjugate imaginary collineations (in point co-ordinates) was a novelty that seemed capable of a generalization which I sought in vain at that time. also desirable to invert the transformations. This inversion was accomplished for some of the transformations, but not for all, although it was evident that they were really birational. I had always intended to investigate the inversion of quadratic transformations in general, but a press of other work had caused the subject to be abandoned until very recently, when Dr. Dickson's interesting construction of a special transformation recalled my interest to this field.

The main object of this paper was to have been the inversion of the general quadratic transformation, which is accordingly presented at the close of the paper. But the method of treatment led me also to the generalization mentioned above, furnishing a simple geometrical construction for the general transformation, and this is to be found in § 2.

Transformations in the reduced form.

That a quadratic transformation

(I) $\rho y_1 = \phi(x_1, x_2, x_3), \rho y_2 = \psi(x_1, x_2, x_3), \rho y_3 = \chi(x_1, x_2, x_3)$ shall admit a rational inversion, it is necessary and suffi-

¹ "Ueber die zu der Curve: $\lambda^3 \mu + \mu^3 \nu + \nu^3 \lambda = 0$ im projectiven Sinne gehörende mehrfache Ueberdeckung der Ebene."-American Journal of Mathematics, Vol. XIII, 1890.

² L. E. Dickson, "A quadratic Cremona transformation defined by a conic."-Rendiconti del Circolo Matematico di Palermo, T. IX, 1895. See also his paper in the current volume of the Proceedings of the California Academy of Sciences. January 31, 1898.

cient that the three conics $\phi = o$, $\psi = o$ and $\chi = o$ have three points, and only three, in common. If these points be all distinct (and of course not collinear) and the equations of the lines joining them in pairs be $\lambda = o$, $\mu = o$, $\nu = o$, then the equation of any conic through the three points must be of the form

$$p\mu\nu + q\nu\lambda + r\lambda\mu = o,$$

and the formulæ of transformation may be written in what we shall call the reduced form:

(2)
$$\rho y_i = p_i \mu \nu + q_i \nu \lambda + r_i \lambda \mu, (i = 1, 2, 3).$$

When the formulæ are given in this form, it is clear that the general quadratic transformation is equivalent to the product $S_1 Q S_2$ of a linear transformation S_1 , of what we may call a *normal* quadratic transformation Q, and of a second linear transformation S_2 . I append the explicit formulæ of these transformations:

(3)
$$S_1$$
: $\rho \lambda = l_1 x_1 + l_2 x_2 + l_3 x_3$
 $\rho \mu = m_1 x_1 + m_2 x_2 + m_3 x_3$
 $\rho \nu = n_1 x_1 + n_2 x_2 + n_3 x_3$
(4) Q : $\sigma Y_1 = \mu \nu$, $\sigma Y_2 = \nu \lambda$, $\sigma Y_3 = \lambda \mu$
 $\tau y_1 = p_1 Y_1 + q_1 Y_2 + r_1 Y_3$
(5) S_2 : $\tau y_2 = p_2 Y_1 + q_2 Y_2 + r_2 Y_3$
 $\tau y_3 = p_3 Y_1 + q_3 Y_2 + r_3 Y_2$

The transformation can now be readily inverted, for the transformation inverse to $S_1 Q S_2$ is $S_2^{-1} Q^{-1} S_1^{-1}$, where S_2^{-1} , Q^{-1} , S_1^{-1} are given by the formulæ:

(6)
$$S_2^{-1}$$
: $\rho Y_1 = P_1 y_1 + P_2 y_2 + P_3 y_3$
 $\rho Y_2 = Q_1 y_1 + Q_2 y_2 + Q_3 y_3$
 $\rho Y_3 = R_1 y_1 + R_2 y_2 + R_3 y_3$

 P_1 , Q_1 , etc., denoting as usual the co-factors of p_1 , q_1 , etc., in the determinant of S_2 , viz.:

$$(p q r) = \begin{vmatrix} p_1 q_1 r_1 \\ p_2 q_2 r_2 \\ p_3 q_3 r_3 \end{vmatrix}$$

(7)
$$Q^{-1}$$
: $\sigma \lambda = \Upsilon_2 \Upsilon_2$, $\sigma \mu = \Upsilon_3 \Upsilon_1$, $\sigma \nu = \Upsilon_1 \Upsilon_2$
 $\tau \kappa_1 = L_1 \lambda + M_1 \mu + N_1 \nu$

(8)
$$S_1^{-1}$$
: $\tau x_2 = L_2 \lambda + M_2 \mu + N_2 \nu$
 $\tau x_3 = L_3 \lambda + M_3 \mu + N_3 \nu$

Compounding these formulæ, the inverse transformation may be conveniently written:

$$\rho x_{1} = L_{1} Y_{2} Y_{3} + M_{1} Y_{3} Y_{1} + N_{1} Y_{1} Y_{2} \equiv \Phi (y_{1}, y_{2}, y_{3})$$

$$(9) \rho x_{2} = L_{2} Y_{2} Y_{3} + M_{2} Y_{3} Y_{1} + N_{2} Y_{1} Y_{2} \equiv \Psi (y_{1}, y_{2}, y_{3})$$

$$\rho x_{3} = L_{3} Y_{2} Y_{3} + M_{3} Y_{3} Y_{1} + N_{3} Y_{1} Y_{2} \equiv X (y_{1}, y_{2}, y_{3})$$

The above inversion is of course sufficiently simple, but I have preferred to write out the formulæ in detail, as some of the results will be convenient for comparison in the investigation of transformations in the general form which is to follow.

§ 2. Geometrical theorems and constructions.

Before proceeding to the problem of the inversion of transformations given in the general form, I will point out that the formulæ of § I lead to a theorem which seems to me to be a fundamental theorem in the geometrical theory of quadratic transformations.

From (7) we have

(10)
$$\lambda: \nu = \Upsilon_3: \Upsilon_1 \text{ and } \mu: \nu = \Upsilon_3: \Upsilon_2.$$

Hence, to the intersection of

(11)
$$\lambda - k \nu = 0 \text{ and } \mu - k' \nu = 0$$

corresponds the intersection of

(12)
$$\Upsilon_3 - k \Upsilon_1 = o \text{ and } \Upsilon_3 - k' \Upsilon_2 = o,$$

where k and k' may have any values whatever. But $\lambda - k \nu = o$ and $\Upsilon_3 - k \Upsilon_1 = o$ represent for variable k two homographic pencils, while $\mu - k' \nu = o$ and $\Upsilon_3 - k' \Upsilon_2 = o$ represent a second pair of homographic pencils. A slight generalization of these formulæ leads us to the following:

THEOREM I: Let A and A' be homographic pencils of rays, and let B and B' be two other homographic pencils of rays. If to each intersection of a ray of A with a ray of B correspond the intersection of the corresponding rays of A' and B', this correspondence can be represented by a quadratic transformation.

The transformation is evidently birational, and the most general birational quadratic transformation can be represented in this way. It might indeed seem at first that the position of the pencils is slightly too general, but this is not the case. For, denoting the rays of the various pencils by

(13) (A)
$$p - \lambda q = 0$$
; (A') $k - \lambda l = 0$;
(B) $r - \mu t = 0$; (B') $m - \mu n = 0$,

it is easily shown that

$$(\lambda_1 - \lambda_2) (p - \lambda q)$$

$$\equiv (\lambda - \lambda_2) (p - \lambda_1 q) - (\lambda - \lambda_1) (p - \lambda_2 q),$$

with like formulæ for the other pencils. If now we choose λ_1 , λ_2 , μ_1 , μ_2 so that

$$\begin{array}{l}
p - \lambda_2 q \equiv r - \mu_2 t \equiv g \\
k - \lambda_1 l \equiv m - \mu_1 n \equiv h
\end{array}$$

and furthermore write

$$\frac{\lambda-\lambda_1}{\lambda-\lambda_2}=\lambda'\quad \frac{\mu-\mu_1}{\mu-\mu_2}=\mu',$$

then formulæ (13) become

(14)
$$(p - \lambda_1 q) - \lambda' g = o; (A') h - \lambda' (k - \lambda_2 l) = o; (B) (r - \mu_1 t) - \mu' g = o; (B') h - \mu' (m - \mu_2 n) = o,$$

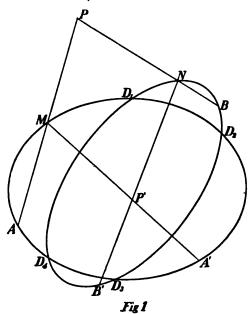

and these are of the same form as (11) and (12).

Theorem I can also be proved directly without difficulty by the method of synthetic geometry. To a ray of A or of B corresponds a ray of A' or of B' respectively. But a straight line in general will be generated by pencils A and B in perspective. The corresponding pencils A' and B'

are then homographic, and generate a conic. But the birational one-to-one correspondence in which a straight line in general is converted into a conic is a quadratic Cremona transformation.

Since a pair of homographic pencils determine a conic through their vertices as the locus of the intersections of corresponding rays, and, vice versa, a conic determines a pair of homographic pencils whose vertices are any two points of the conic, we can restate Theorem I in a form which may be more convenient for practical work:

THEOREM II: Let a and β be any two conics. Let A and A' be any two points on a, B and B' any two points on β . P and P' are corresponding points in a birational quadratic transformation if PA and P'A' meet on a, while PB and P'B' meet on β .

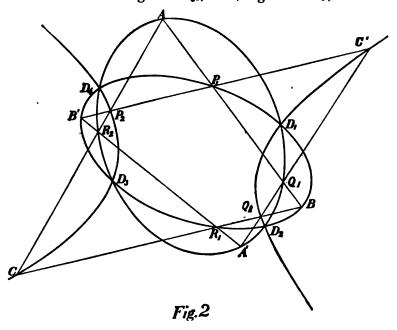

The construction is illustrated by fig. 1. The four points, D_1 , D_2 , D_3 , D_4 , in which a and β meet are evidently self-corresponding points of the transformation. They are in general the only such points, but if a and β coincide, all

the points of these coincident conics are self-corresponding. This special case is Dr. Dickson's transformation.

A and B are vertices of one of the fundamental triangles, A' and B' the corresponding vertices of the other. The remaining vertices C and C' are readily found by the following construction (see fig. 2):

Let AB meet a again in Q_1 , and β again in P_1 ; let A'B

meet a again in R_2 and β again in R_1 . Then $A R_2$ and $B R_1$ meet in C, and $A' Q_1$, and $B' P_1$ meet in C'.

It is obvious that C and C' will lie on a third conic γ through D_1 , D_2 , D_3 , D_4 . In the case of Dr. Dickson's transformation, however, where a and β coincide, the above construction shows that C and C' coincide, being the intersection of A B' and A' B.

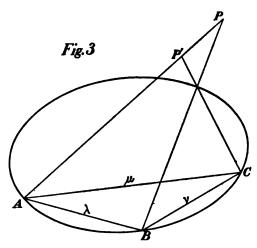

Finally, the transformation is fully determined if the double points D_1 , D_2 , D_3 , D_4 and the vertices of one of the fundamental triangles, say A, B, C, be given. These points suffice to determine the conics a, B and γ . The vertices of the other triangle can be found by the following

theorem, which is easily deduced from the relations given above:

THEOREM III: Let a, β , γ be three conics of a pencil through four points, and let A, B, C be three points chosen arbitrarily on a, β , γ respectively. Let AB meet a again in Q_1 and β again in P_1 ; let BC meet β again in R_1 and γ again in Q_2 ; let CA meet γ again in P_2 and a again in R_2 . Then P_1P_2 , Q_1Q_2 , R_1R_2 are the sides of a triangle whose vertices A'B'C' lie on a, β , γ respectively.

This construction is illustrated in Figure 2.

A simple construction for a special case in which, as in Dr. Dickson's transformation, there is a self-corresponding conic, is shown in Fig. 3. A, B and C are any three points on a conic. All pairs of corresponding points P

and P^1 are collinear with A. Furthermore, PB and P'C meet on the conic. All points on the conic evidently correspond to themselves. A counts twice as a vertex of each fundamental triangle, B and C are the other vertices. If $\lambda:\mu:\nu$ are the co-ordinates of P with reference to the triangle ABC, $\lambda':\mu':\nu'$ those of P' and $\mu\nu+\nu\lambda+\lambda\mu=0$ the equation of the conic, the formulæ of the transformation will be

$$\lambda': \mu': \nu' = \mu (\nu + \lambda): -\mu \nu: -\nu^2$$

and those of the inverse transformation will be

$$\lambda : \mu : \nu = \nu' (\lambda' + \mu') : -\mu'^2 : -\mu' \nu'.$$

§ 3. Transformations in the general form.

Suppose the formulæ of transformation to be given in the general form

$$\rho \ y_1 = \phi \ (x_1, x_2, x_3) \equiv a_1 x_1^2 + b_1 x_2^2 + c_1 x_3^2 + 2 f_1 x_2 x_3 + 2 g_1 x_3 x_1 + 2 h_1 x_1 x_2
\rho \ y_2 = \psi \ (x_1, x_2, x_3) \equiv a_2 x_1^2 + b_2 x_2^2 + c_2 x_3^2 + 2 f_2 x_3 + 2 g_2 x_3 x_1 + 2 h_2 x_1 x_2
\rho \ y_3 = \chi \ (x_1, x_2, x_3) \equiv a_3 x_1^2 + b_3 x_2^3 + c_3 x_3^2 + 2 f_3 x_2 x_3 + 2 g_3 x_3 x_1 + 2 h_3 x_1 x_2$$

It is then in given cases frequently very difficult to transmute these formulæ into the reduced form (3), even when we know that they are really birational. The Jacobian of ϕ , ψ , χ must have a double point at each of their intersections, and must therefore degenerate into the triangle of which these intersections are the vertices; that is to say, the equation of the Jacobian will be

$$k \lambda \mu \nu = o$$
.

The test that the Jacobian shall so degenerate, is that its Hessian shall do likewise, so that the coefficients of the Jacobian and of its Hessian must be proportional. But, supposing this test to be satisfied, it is usually by no means easy to factor the Jacobian. The formulæ of the inverse transformation can however be established in another way, without actually finding the coefficients of the reduced form (3), and to accomplish this is the object of the present paper.

If we write $\lambda = 0$ in equations (3), we find

$$y_1: y_2: y_3 = p_1: p_2: p_3.$$

Similarly, $\mu = o$ gives

$$y_1:y_2:y_3=q_1:q_2:q_3$$

and v = o gives

$$y_1:y_2:y_3=r_1:r_2:r_3$$
.

In other words, the sides of the triangle λ , μ , ν are converted into the above three points by the transformation. These points are then the vertices of the triangle $\Upsilon_1 \Upsilon_2 \Upsilon_3$; that is to say, they are the three points common to the conics $\Phi = o$, $\Psi = o$, X = o of the inverse transformation. Indeed, this can readily be seen by substituting the co-ordinates of these points in (6). Our first problem will be to establish the equations which determine these co-ordinates.

Again, writing
$$x_2 = 0$$
, $x_3 = 0$ in (15), we find $y_1 : y_2 : y_3 = a_1 : a_2 : a_3$.

In other words, $\Psi = o$ and X = o meet also in the point $(a_1 : a_2 : a_3)$. Similarly, X = o and $\Phi = o$ meet also in $(b_1 : b_2 : b_3)$, and $\Phi = o$ and $\Psi = o$ meet in $(c_1 : c_2 : c_3)$. We have therefore found five points on each of these conics.

In what follows, we shall frequently denote these points by the single letters p, q, r, a, b, c.

§ 4. Determination of the equations for p, q, r.

We have just seen that the points p, q, r are the fundamental points of the inverse transformation. Our first problem is therefore to establish the equations for these points. We shall find that it will not be necessary to solve the equations, but that they appear directly in the formulæ of the inverse transformation.

A comparison of the general form (15) with the reduced form (3) gives us the following identities:

$$a_{1} = p_{1} m_{1} n_{1} + q_{1} n_{1} l_{1} + r_{1} l_{1} m_{1}$$

$$b_{1} = p_{1} m_{2} n_{2} + q_{1} n_{2} l_{2} + r_{1} l_{2} m_{2}$$

$$c_{1} = p_{1} m_{3} n_{3} + q_{1} n_{3} l_{3} + r_{1} l_{3} m_{3}$$

$$2 f_{1} = p_{1} (m_{2} n_{3} + m_{3} n_{2}) + q_{1} (n_{2} l_{3} + n_{3} l_{2}) + r_{1} (l_{2} m_{3} + l_{3} m_{2})$$

$$2 g_{1} = p_{1} (m_{3} n_{1} + m_{1} n_{3}) + q_{1} (n_{3} l_{1} + n_{1} l_{3}) + r_{1} (l_{3} m_{1} + l_{1} m_{3})$$

$$2 h_{1} = p_{1} (m_{1} n_{2} + m_{2} n_{1}) + q_{1} (n_{1} l_{2} + n_{2} l_{1}) + r_{1} (l_{1} m_{2} + l_{2} m_{1})$$

with similar identities for the other coefficients.

Solving these equations for the quantities $m_1 n_1$, $m_2 n_2$, etc., we have, denoting again by (pqr) the determinant of the transformation S_2 , and by P_1 , P_2 , etc., the co-factors of p_1 , p_2 , etc., in that determinant:

From these identities we readily deduce the following:

$$(p q r)^{2} n_{2} n_{3} (l_{3} m_{2} - l_{2} m_{3}) = P_{b} Q_{c} - P_{c} Q_{b} \equiv (p q r) (r b c)$$

$$(p q r)^{2} n_{2}^{2} (l_{3} m_{2} - l_{2} m_{3}) = 2 (P_{b} Q_{t} - P_{t} Q_{b}) \equiv 2 (p q r) (r b f)$$

$$(p q r)^{2} n_{3}^{2} (l_{3} m_{2} - l_{2} m_{3}) = 2 (P_{t} Q_{c} - P_{c} Q_{t}) \equiv 2 (p q r) (r f c)$$

and a comparison of the left-hand members leads immediately to the result:

(19)
$$(rbc)^2 = 4(rbf)(rfc).$$

In the same way we can show that

(20)
$$(rca)^2 = 4(rcg)(rga),$$

and finally that

$$(21) (rab)^2 = 4 (rah) (rhb).$$

But a slight consideration of the symmetry of the identities (16) and (17), shows us that equations (19), (20) and (21) are equally true if either p or q be substituted for r, and hence that the three conics

$$(y b c)^{2} - 4 (y b f) (y f c) = 0$$

$$(y c a)^{2} - 4 (y c g) (y g a) = 0$$

$$(y a b)^{2} - 4 (y a h) (y h b) = 0$$

all pass through the three points p, q and r.

We can then infer that the conics $\Phi = o$, $\Psi = o$ and

X = o of the inverse transformation are at most linear functions of the conics of (22). We shall see that they are identical with the latter.

§ 5. Identification of the equations just obtained with those of the inverse transformation.

From the form of equations (22), we see that the first of these equations is also satisfied by the points b and c, the second by c and a, the third by a and b. But these are exactly the conditions which were to be satisfied (§ 3) by the curves $\Phi = o$, $\Psi = o$, X = o.

The left-hand members of equations (22) are therefore, except for eventual numerical factors, identical with the forms Φ , Ψ , X of the inverse transformation.

These factors shall now be determined. Let

$$\rho x_1 = k_1 [(y b c)^2 - 4 (y b f) (y f c)]
\rho x_2 = k_2 [(y c a)^2 - 4 (y c g) (y g a)]
\rho x_3 = k_3 [(y a b)^2 - 4 (y a h) (y h b)]$$

The consideration of a single pair of corresponding points will be sufficient to determine the ratios of $k_1 : k_2 : k_3$. Let us write $y_1 : y_2 : y_3 = 1 : o : o$, when

$$\rho x_1 = k_1 \left[(b_2 c_3 - b_3 c_2)^2 - 4 (b_2 f_3 - b_3 f_2) (f_2 c_3 - f_3 c_2) \right]
(24) \rho x_2 = k_2 \left[(c_2 a_3 - c_3 a_2)^2 - 4 (c_2 g_3 - c_3 g_2) (g_2 a_3 - g_3 a_2) \right]
\rho x_3 = k_3 \left[(a_2 b_3 - a_3 b_2)^2 - 4 (a_2 h_3 - a_3 h_2) (h_2 b_3 - h_3 b_2) \right]$$

which can be reduced by substituting from (16) into

$$\rho x_{1} = -k_{1} L_{1} M_{1} N_{1} (L_{1} Q_{1} R_{1} + M_{1} R_{1} P_{1} + N_{1} P_{1} Q_{1})$$

$$\rho x_{2} = -k_{2} L_{2} M_{2} N_{2} (L_{2} Q_{1} R_{1} + M_{2} R_{1} P_{1} + N_{2} P_{1} Q_{1})$$

$$\rho x_{3} = -k_{3} L_{3} M_{3} N_{3} (L_{3} Q_{1} R_{1} + M_{3} R_{1} P_{1} + N_{3} P_{1} Q_{1})$$

But, substituting $y_1: y_2: y_3 = 1: o: o$ in formulæ (9), the equivalent of (23), and comparing the result with (25), we find that

(26)
$$k_1 L_1 M_1 N_1 = k_2 L_2 M_2 N_2 = k_3 L_3 M_3 N_3$$
.

January 31, 1898.

It is now easy to show by means of (16) that

$$\begin{array}{ll}
2 (b f c) = (p q r) L_1 M_1 N_1 \\
2 (c g a) = (p q r) L_2 M_2 N_2 \\
2 (a h b) = (p q r) L_3 M_3 N_3
\end{array}$$

and hence by (26) that

$$k_1: k_2: k_3 = (b f c)^{-1}: (c g a)^{-1}: (a h b)^{-1}$$

Substituting these values in (23) we have the formulæ of the inverse transformation in the following final form:

$$\rho x_1 = (b f c)^{-1} [(y b c)^2 - 4 (y b f) (y f c)]
\rho x_2 = (c g a)^{-1} [(y c a)^2 - 4 (y c g) (y g a)]
\rho x_3 = (a h b)^{-1} [(y a b)^2 - 4 (y a h) (y h b)]$$

With these formulæ the object of the present paper is accomplished. The method will fail in special cases, but in such cases the numerical relations between the coefficients are always such as to make the inversion by other methods comparatively easy. For instance, we see by (28) that the point f is the polar of the line b c with respect to $\Phi = o$. Now if it happen that f lies on this line our formula for Φ may vanish identically; but in this case evidently Φ degenerates into two lines of which b c is one. Again, the method will sometimes fail when two of the points p, q, r coincide; but in this case the Jacobian has a square factor, which can therefore readily be found, and the formulæ reduced at once.

THE QUADRATIC CREMONA TRANSFORMATION.

BY LEONARD E. DICKSON, PH. D.,

Instructor in Mathematics, University of California.

I. THE importance of the quadratic Cremona (i. e., birational) transformation is enhanced by the fact that any Cremona transformation of arbitrary order can be obtained by applying a succession of quadratic ones. The theorem that the deficiency of an algebraic curve is unchanged under a Cremona transformation thus requires proof only for quadratic transformations.

A quadratic transformation T

$$x':y':z'=U(x,y,z):V(x,y,z):W(x,y,z)$$

will be birational (i. e., to any point x':y':z' will correspond but one point x:y:z) if and only if the three conics U=o, V=o, W=o have in common three points of intersection, say I_1 , I_2 , I_3 , called principal points. The most general correspondence thus required between the straight lines of one plane and the conics through three fixed points in a second plane may be obtained geometrically by Steiner's Construction. An arbitrary line of the first plane, together with two fixed lines a and b not lying in either plane, determine an hyperboloid of one sheet which is cut by the second plane in a conic passing through three fixed points, one on a, one on b, and a third on that line of the first plane meeting both a and b.

In applications to the resolution of higher singularities of plane curves, we desire geometric constructions in a single plane.

2. Analytic reduction of T to a normal type Q.

By a proper choice of p:q:r, the line px+qy+rz=o is transformed by T^{-1} (the inverse of T) into a conic pU+qV+rW=o which breaks up into a pair of lines through

[13]

January 31, 1898.

 I_1 , I_2 I_3 . Thus if the latter are distinct points, we can find three lines

$$\xi = p_1 x + q_1 y + r_1 z = 0$$

$$\eta = p_2 x + q_2 y + r_2 z = 0$$

$$\zeta = p_3 x + q_3 y + r_3 z = 0$$

which T^{-1} transforms into the degenerate conics $L_2 \cdot L_3 = o$, $L_1 \cdot L_2 = o$ respectively, where L_1 (x, y, z) = o is the line joining I_2 with I_3 , etc. We may write, after solving (1),

$$L_i(x, y, z) \equiv \lambda_i(\xi, \eta, \zeta) \quad (i = 1, 2, 3).$$

Hence

(2) $\rho \xi \equiv \rho (p_1 x' + q_1 y' + r_1 z') = p_1 U + q_1 V + r_1 W = L_2 \cdot L_8 \equiv \lambda_2 \cdot \lambda_8$, and similarly for η' and ζ' . Thus T written in the coördinates ξ , η , ζ becomes

(3)
$$\xi':\eta':\zeta'=\lambda_2\,\lambda_3:\lambda_1\,\lambda_3:\lambda_1\,\lambda_2,$$

which we denote as the transformation \overline{T} , geometrically identical with T. If S denotes the linear transformation [see (1)]:

$$\rho \xi = p_1 x + q_1 y + r_1 z, \text{ etc.,}$$

$$\overline{T} = S^{-1} T S :$$

we have

for S^{-1} transforms the point $(\xi:\eta:\zeta)$ into (x:y.z), which T transforms into (x':y':z'), which finally S transforms to $(\xi':\eta:\zeta')$, the intermediate eliminations being expressed by (2).

To obtain a further reduction, denote by S_1 the linear transformation

$$\xi' = \lambda_1 \ (\xi, \, \eta, \, \zeta), \ \dot{\eta} = \lambda_2 \ (\xi, \, \eta, \, \zeta), \ \zeta = \lambda_8 \ (\xi, \, \eta, \, \zeta).$$

Then $S_1^{-1} \overline{T}$ becomes the normal type of transformation Q:

$$\xi': \eta: \zeta' = \eta \zeta: \xi \zeta: \xi \eta = \frac{1}{\xi}: \frac{1}{\eta}: \frac{1}{\zeta},$$

as we may readily verify that $\overline{T} = S_1 Q$.

The most general quadratic Cremona transformation with three distinct principal points may thus be written

$$T = S S_1 Q S^{-1}.$$

3. An elegant geometric construction for T follows readily from (3) as remarked recently by Prof. Haskell.¹

Thus
$$\lambda_2 (\lambda_3 - \rho \lambda_1) = o, \lambda_1 (\lambda_3 - \sigma \lambda_2) = o$$

are transformed by (3) into respectively

$$\xi - \rho \zeta = 0$$
, $\eta - \sigma \zeta = 0$.

Hence if we set up two projective pencils

$$\lambda_8 - \rho \lambda_1 = o, \xi - \rho \zeta = o$$

by means of a conic, and similarly for the second pair of pencils, we find for an arbitrary point, determined as the intersection of the rays $\lambda_8 - \rho' \lambda_1 = o$, $\lambda_8 - \sigma' \lambda_2 = o$, the transformed point by taking the intersection of the transformed rays $\xi - \rho' \zeta = o$, $\eta - \sigma' \zeta = o$.

4. The normal type of transformation Q transforms $a \xi + b \eta + c \zeta = o$ into $a \eta \zeta + b \xi \zeta + c \xi \eta = o$.

In particular, the line $b \eta + c \zeta = o$ through a vertex is transformed into the line-pair $\xi = o$, $b \zeta + c \eta = o$, the latter evidently making with the sides $\eta = o$, $\zeta = o$ angles equal to those made by the given line. The vertex $\zeta = \eta = o$ is transformed into $\xi = o$, the side opposite. Neglecting the vertices, every bisector of an interior or exterior angle of the triangle is a self-corresponding line.

If we make the construction on a sphere, we have a simple division into forty-eight compartments by the sides and bisectors. Each of the four centers of the inscribed and escribed circles of the triangle of reference and each of the four analogous points for the symmetrical triangle is a vertex for six triangular compartments. These eight centers are the fixed points under Q, which produces a "projective rotation" through 180° of the six compartments about each center.

5. An immediate generalization of the transformation Q is obtained by making a correspondence between any point

¹Proc. Cal. Acad. Sci., 3d Ser., Math.-Physics, Vol. I.

P and the intersection P' of the straight lines harmonically separated from P by each pair of opposite sides of a complete quadrilateral $A \ C \ B \ D$. Taking its diagonal triangle $G \ E \ F$ as our triangle of reference, viz.:

$$GF \equiv x = o$$
, $FE \equiv y = o$, $EG \equiv z = o$,

the vertices of the quadrilateral may be defined by

$$A(a:b:c), B(-a:b:c), D(a:b:-c), C(a:-b:c).$$

The line GP' separated from $P(x_1: y_1: z_1)$ and hence from GP, viz.,

$$x - \frac{x_1}{z_1} z = o$$
, harmonically by

$$GD: x + \frac{a}{c}z = o$$
, $GA: x - \frac{a}{c}z = o$

has the equation

$$x - \frac{a^2}{c^2} \frac{z_1}{x_1} \cdot z = o.$$

Similarly for $FP': x - \frac{a^2}{b^2} \frac{y_1}{x_1} \cdot y = o$.

Hence P' has the coördinates

$$\frac{a^2}{x_1}:\frac{b^2}{y_1}:\frac{c^2}{z_1}.$$

The only fixed points are the four vertices. If one of these should be the unit point 1:1:1, the transformation is Q.

6. Another normal type of quadratic Cremona transformation is defined geometrically by keeping fixed one pair of opposite sides of a hexagon inscribed in a given "base conic" and making correspond the two variable points of intersection of the other two pairs of opposite sides. Let the fixed pair, A C and D B, intersect in the point O, and take as triangle of reference:

$$DO \equiv \xi = o$$
, $AO \equiv \eta = o$, $AD \equiv \zeta = o$.

and as base conic $a \xi \eta + b \xi \zeta + c \eta \zeta + d \zeta^2 = o$.

¹L. E. Dickson, Rendicouti del Circolo Matematico di Palermo, Vol. IX, 1895; also, American Mathematical Mouthly, 1895.

The point $P'(\xi':\eta:\zeta')$ corresponding by the construction to $P(\xi:\eta:\zeta)$ is readily found to have the coördinates ¹

$$T_1: \qquad \xi': \eta': \zeta' = \xi \zeta: \eta \zeta: (-1/d) \ (a \xi \eta + b \xi \zeta + c \eta \zeta).$$

The vertices and sides of triangle A O D are transformed into the sides and vertices of triangle C O B. Repeating the transformation, we find for T_1^2 :

$$\xi' = \xi, \ \dot{\eta} = \eta, \ \zeta' = \frac{a}{\frac{a}{\xi} + \frac{b}{\eta} + \frac{c}{\xi}} - \frac{(b \ \xi + c \eta)}{d},$$

the proportionality factor in T_1 dropping out of T_1^2 .

The point which T_1^2 leaves fixed are given by

$$(\delta \xi + c \eta) (a \xi \eta + \delta \xi \zeta + c \eta \zeta + d \zeta^2) = o,$$

viz., the base conic and the line OK joining O to the intersection K of AD and BC, upon which therefore an involution is marked out by T_1 . For the special case b=c=o, when C coincides with A, B with D, we have Hirst's Construction², by which P and P' are conjugate points with respect to the base conic; thus $T_1^2=1$ in this case.

In general, if S' is the linear transformation

$$\xi': \eta: \zeta' = \eta: \xi: \frac{-1}{a} (b \xi + c \eta + d \zeta)$$

we find that $T_1 S'$ reduces to the normal type Q.

7. Investigation of the most general quadratic Cremona transformation,

$$T: \quad x' = \frac{U(x, y)}{W(x, y)}, \quad y' = \frac{V(x, y)}{W(x, y)}$$

such that corresponding points P: (x, y) and P': (x', y') are

¹I exclude the trival case s = o, since then the whole plane is transformed into BC, a part of the degenerate base conic. Also I exclude d = o, when O is on the base conic. If A and B have coincided (viz.: at O), every point of the plane is transformed into the base conic; if C and B have coincided (viz.: with O), every point is transformed with the single point O. Not trivial are the cases when D and C, or when C and C, coincide at C. The two cases are quite analogous. For either, the transformation and its inverse have but two distinct principal points. The formulæ are readily obtained, taking for example C as triangle of reference.

² Cf. Scott, "Modern Analytical Geometry," pp. 219-224.

collinear with a given point O:(a,b). We must then have identically in x and y:

(1)
$$\frac{x-a}{y-b} \equiv \frac{x'-a}{y'-b} \equiv \frac{U-aW}{V-bW}$$

Hence there must exist a linear function L(x, y) such that

(2)
$$U = a W \equiv (x - a) L$$
; $V = b W \equiv (y - b) L$

from which,
$$bU-aV \equiv (bx-ay)L$$
.

For the case in which U=o, V=o, W=o have three distinct points of intersection, these can not all lie on L=o, since T would then reduce to a linear transformation. Hence one point of intersection is O:(a,b) and the other two lie on L=o, say A and D. Hence by virtue of (2) our transformation T may be written

(3)
$$x'-a=\frac{(x-a) L}{W}, y'-b=\frac{(y-b) L}{W}.$$

The line L = o is transformed into the point (a, b), so that the the latter is not fixed. Hence the fixed points of (3) all lie on the "base conic,"

$$(4) W=L.$$

T contains nine arbitrary constants, depending on the arbitrary point (a, b), the arbitrary conic through it

(5)
$$W \equiv a (x-a)^2 + \beta (x-a) (y-b) + \gamma (y-b)^2 + \delta (x-a) + \epsilon (y-b) = 0,$$

and the arbitrary points A and D on W=o (distinct and different from O) to determine the line L=o. We will fix A and D as the intersections of W=o with

(6)
$$\begin{array}{ccc} OA: & X \equiv p_1 (x-a) + q_1 (y-b) = o \\ OD: & Y \equiv p_2 (x-a) + q_2 (y-b) = o \end{array}$$

Solving,
$$\begin{cases} \rho(x-a) = q_2 X - q_1 Y \\ \rho(y-b) = -p_2 X + p_1 Y \end{cases} \quad \rho = p_1 q_2 - p_2 q_1$$

Hence (7)
$$W \equiv a_2 X^2 + \lambda X Y + a_1 Y^2 + \delta_2 X - \delta_1 Y = 0$$

where

$$\begin{cases} a_1 \equiv a q_1^2 - \beta p_1 q_1 + \gamma p_1^2, & \delta_1 \equiv \rho (\delta q_1 - \epsilon p_1) \\ a_2 \equiv a q_2^2 - \beta p_2 q_2 + \gamma p_2^2, & \delta_2 \equiv \rho (\delta q_2 - \epsilon p_2) \\ \lambda \equiv \beta (p_1 q_2 + p_2 q_1) - 2 a q_1 q_2 - 2 \gamma p_1 p_2 \end{cases}$$

For the X, Y coördinates of A and D we have

$$A: \left(\frac{-\delta_2}{a_2}, o\right); D: \left(o, \frac{\delta_1}{a_1}\right)$$

so that the equation to AD is

$$L \equiv \frac{a_1}{\delta_1} \Upsilon - \frac{a_2}{\delta_2} X - \mathbf{I} = 0,$$

the multiplicative constant in L/W of (3) being taken into W. The base conic W=L is met by X=o and Y=o in respectively

$$B: \left(o, \frac{1}{\delta_1}\right); C: \left(\frac{-1}{\delta_2}, o\right).$$

Our transformation (3) becomes for the X, Y coördinates:

(3')
$$X' = \frac{L(X, \Upsilon)}{W(X, \Upsilon)} \cdot X$$
, $\Upsilon' = \frac{L(X, \Upsilon)}{W(X, \Upsilon)} \cdot \Upsilon$.

We may verify that AP and BP' meet in a point on the base conic (4), From Pascal's Theorem on the inscribed hexagon, it follows that DP and CP' meet on this base conic. We may thus invert the relations (3') by interchanging A with C, B with D, and P with P', the base conic remaining fixed, viz.:

$$a_2 X^2 + \lambda X Y + a_1 Y^2 - L - M - I = 0$$

where the equation of B C has been written in the form

$$M \equiv \delta_1 \Upsilon - \delta_2 X - \mathbf{I} = o$$
.

We have therefore to replace in (3') δ_1 by $\frac{a_1}{\delta_1}$, δ_2 by $\frac{a_2}{\delta_2}$

(leaving a_2 , λ and a_1 unchanged) and interchange X with X', Y with Y'.

Hence

$$(3'_1) \quad X = \frac{M(X', \Upsilon')}{W_1(X', \Upsilon')} \cdot X', \quad \Upsilon = \frac{M(X', \Upsilon')}{W_1(X', \Upsilon')} \cdot \Upsilon'$$

where

$$W_1(X', \Upsilon') \equiv a_2 X'^2 + \lambda X' \Upsilon' + a_1 \Upsilon' + \frac{a_2}{\delta_2} X' - \frac{a_1}{\delta_1} \Upsilon'.$$

To pass now to the inverse of our transformation (3), we note that

$$\begin{array}{c} \delta_{1} \ \varUpsilon'-\delta_{2} \ X'-1 = -\rho^{2} \delta \ (x'-a)-\rho^{2} \epsilon \ (y'-b)-1 \\ a_{2} \ X'^{2}+\lambda \ X' \ \varUpsilon'+a_{1} \ \varUpsilon'^{2} = \rho^{2} \left[a \ (x'-a)^{2}+\beta (x'-a) \ (y'-b)+\gamma \ (y'-b)^{2}\right] \\ \frac{a_{2}}{\delta_{2}} \ X'-\frac{a_{1}}{\delta_{1}} \ \varUpsilon' = \\ (x'-a) \left\{ \frac{a \delta q_{1} q_{2}-a \epsilon \left(p_{1} q_{2}+q_{1} p_{2}\right)+(\beta \epsilon-\gamma \delta) p_{1} p_{2}}{(\delta q_{1}-\epsilon p_{1}) \left(\delta q_{2}-\epsilon p_{2}\right)} \right\} \\ + (y'-b) \ \left\{ \frac{(a \epsilon-\beta \delta) q_{1} q_{2}+\gamma \delta \left(p_{1} q_{2}+q_{1} p_{2}\right)-\gamma \epsilon p_{1} p_{2}\right)}{(\delta q_{1}-\epsilon p_{1}) \left(\delta q_{2}-\epsilon p_{2}\right)} \right\}. \end{array}$$

Subtracting I from the last expression on the right, we have L written in x', y'. Taking for convenience $\rho = I$, we have for M in terms of x', y': $M' \equiv -\delta(x'-a) - \epsilon(y'-b) - I$. If now we denote

$$C \equiv a (x-a)^2 + \beta (x-a) (y-b) + \gamma (y-b)^2 - 1$$

our transformation T and its inverse may be written¹

(3)
$$T: x'-a = \frac{(x-a) L}{C-M}, y'-b = \frac{(y-b) L}{C-M}$$

(31)
$$T^{-1}: x'-a = \frac{(x-a)M}{C-L}, y'-b = \frac{(y-b)M}{C-L}.$$

The base conic (every point of which T and T^{-1} leave fixed) has the equation

$$C-M-L=o$$
.

The line joining O to the intersection K of AD with BC is

$$M = L$$
.

An arbitrary straight line

$$(y-b)=m\ (x-a)+l$$

is transformed by T into the conic

$$M \left\{ (y-b)-m(x-a) \right\} = l(C-L).$$

¹The symmetry of the formulæ suggests that we give initially two pairs of points to fix L=a, M=a (introducing eight parameters) and a base conic through these four points (introducing a ninth parameter).

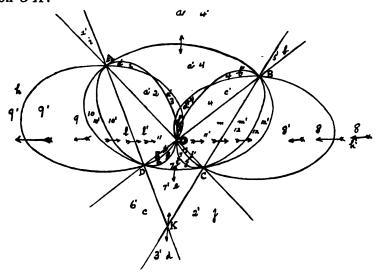

The conic which T transforms into this straight line is

$$L \langle (y-b)-m(x-a) \rangle = l(C-M).$$

These two conics meet in four points given by

$$(L-M) \left\langle (y-b)-m(x-a)-l \right\rangle = 0,$$

two being the intersections of the straight line with the base conic and two lying on OK, viz.: O itself and, say, H. The point H' in which the given line intersects OK and H mutually correspond, so that an involution is marked out on OK.

The compartments of the plane under the transformation T given by (3) and (31) are given in the accompanying figure.

The line BC transforms into a conic tangent to the base conic ABCD at B and C and tangent to OK at O. The conic transforming into AD is tangent to the base conic at A and D and to OK at O.

The line at infinity transforms into the conic C = L (lying at the right in the figure) whose tangent at O is parallel to AD (L = o). The conic C = M (lying at the left) with its tangent at O parallel to BC (M = o) transforms into the line at infinity.

One region, as a, may transform into several, all designated a'; calling them individually 1, 2, 3, 4, they transform into respectively 1', 2', 3', 4'. The arrows on a line through O indicate the directions in which its points are transformed.

Transformations of period two. 8.

The division into compartments is simplest when the correspondence between every pair of corresponding points is mutual, i. e., when the period of the transformation is 2. Let us find the most general quadratic Cremona transformation T of period 2 and having three distinct principal points. The condition that $T = S S_1 Q S^{-1}$ be its own reciprocal is $S_1 Q = Q S_1^{-1}$. Let

$$S_{1} = \begin{cases} \rho x' = a x + b y + c z \\ \rho y' = a' x + b' y + c' z \end{cases} S_{1}^{-1} = \begin{cases} \sigma x = A x' + A' y' + A'' z \\ \sigma y = B x' + B' y' + B'' z' \end{cases} \\ \sigma z = C x' + C' y' + C'' z' \end{cases}$$

For $Q S_1^{-1}$ and $S_1 Q$ we have respectively

$$\lambda x' = \frac{A}{x} + \frac{A'}{y} + \frac{A''}{z}$$
, etc.; $\mu x' = \frac{1}{ax + by + cz}$, etc.

The condition that $S_1 Q = Q S_1^{-1}$ is thus

$$(ax + by + cz) (Ayz + A'xz + A''xy) \equiv (a'x + b'y + c'z) \times (Byz + B'xz + B''xy) \equiv (a''x + b''y + c''z) (Cyz + C'xz + C''xy).$$
 Hence

(1)
$$aA+bA'+cA''=a'B+b'B'+c'B''=a''C+b''C'+c''C''$$

(2)
$$aA' = a'B' = a''C'$$
; (3) $cA' = c'B' = c''C'$;

(2)
$$aA' = a'B' = a''C'$$
; (3) $cA' = c'B' = c''C'$; (4) $aA'' = a'B'' = a''C''$; (5) $bA'' = b'B'' = b''C''$; (6) $bA = b'B = b''C$; (7) $cA = c'B = c''C$.

(6)
$$b A = b' B = b'' C$$
; (7) $c A = c' B = c'' C$.

Case I: $a \ge o$. From (2) and (3), B'B'' = o; from (4) and (5), C''B'' = 0.

(I_a) Suppose first $B' \ge o$. Thus B' = o, C'' = o. (2) and (4), A'=o, a'' C'=o and A''=o, a'=o. Since A' = B' = o, $C' \ge o$. Thus a'' = o. Likewise $A \ge o$. By (5), (6), (3), (7) in turn, b'=o, b=o, c''=o, c=o. Hence S_1 is

$$x':y':z'=ax:c'z:b''y.$$

Thus S_1Q (which is geometrically equivalent to $T = S(S_1Q)S^{-1}$) becomes

$$x':y':z'=\frac{yz}{a}:\frac{xy}{c'}:\frac{xz}{b''}.$$

For b'' = c', z'/y' = z/y, and the transformation is virtually that of Dr. Hirst (§ 6), the fixed conic here being $x^2 - \frac{b''}{a}yz = 0$.

The general case $b'' \ge c'$ is reduced to the latter by first applying the transformation x': y': z' = x: y: az, a = b''/c', which transforms any point P into a point P' such that the cross-ratio

$$\frac{OP}{RP} \stackrel{\bullet}{\bullet} \frac{OP'}{RP'} = a$$

O being the vertex (x = 0, y = 0) and R the intersection of OP with the side z = 0.

(I_b) Suppose however B''=o. Then by (4), A''=o, a''C''=o. Thus $C''\geq o$, a''=o. By (5) b''=o. Thus $B'=ac''\geq o$, so that by (2), a'=o, A'=o. Thus $A\geq o$, whence by (6), b=o. From B''=o, A''=o follows c'=o, c=o. Hence

$$S_1: \qquad x':y':z'=ax:b'y:c''z.$$

Thus
$$S_1Q$$
 becomes $x':y':z'=\frac{yz}{a}:\frac{xz}{b'}:\frac{xy}{c''}$.

If a, b', c' have the same sign, this is the transformation of § 5 by means of harmonic conjugates. If, for example, a alone be negative we apply first the transformation x': y': z' = -x: y: z, which transforms any point P into a point P' separating harmonically the vertex (y = 0, z = 0) and the side opposite, x = 0, from the point P.

Case II: a = o. By a similar investigation we find that S_1 is either x': y': z' = by : a'x: c''z or x': y': z' = cz : b'y: a''x, as the symmetry of the problem for x, y, z would lead us to expect from the result of the case (I_a) .

ON CURVILINEAR ASYMPTOTES.1

BY M. W. HASKELL, PH. D.

Associate Professor of Mathematics, University of California.

The treatment of curvilinear asymptotes in all our textbooks is extremely unsatisfactory. It is sixty years since Plücker² called attention to the defects in Euler's discussion of this subject, and stated clearly the true point of view. With the exception of a single memoir by Stolz³, I have not found any evidence that Plücker's theory has attracted the attention of mathematicians, but this is doubtless due to the fact that the development of projective geometry has diverted the attention of mathematicians from metrical geometry to the undue neglect of the latter.

That Plücker's views have not found a place in our text-books is presumably owing to the lack of a simple method of deriving the results in given numerical cases. For, important and exhaustive as is the memoir of Stolz referred to above, it can not be denied that his method is inconvenient in actual practice, since it depends entirely on expansion in series of decreasing powers. The object of this brief article is to propose a simple method of treatment, which seems to me a natural sequence of Plücker's theory. This method is merely an extension of the partial fractions method for rectilinear asymptotes—a method that is unrivaled for simplicity, but has never received half the attention it deserves.

I. Ordinary rectilinear asymptotes. For this case the method may be summarized as follows. A little fuller treatment can be found in Edwards' Calculus.

Let the equation of a given curve of the nth order be

(1)
$$o = U_n \equiv u_n + u_{n-1} + u_{n-2} + \dots + u_1 + u_o$$
, where U_n , or V_n , W_n , etc., will be used to denote rational

¹ Read before the California Academy of Sciences, Sept. 20, 1897.

² Liouville's Journal, Vol. I, p. 229. See also the first part of Plücker's "Theorie der algebraischen Curven."

⁸ Mathematische Annalen, Vol. XI, p. 41.

integral functions of the n^{th} degree in the co-ordinates, while u_n , u_{n-1} , etc., or v_n , w_n , etc., shall denote homogeneous functions of the degree indicated.

Now, suppose p to be a (unrepeated) linear factor of u_n , say

$$u_{n} \equiv \not p . v_{n-1}.$$

Then, by the method of partial fractions, we can find

(3)
$$\frac{u_{n-1}}{u_n} = \frac{a}{p} + \frac{v_{n-2}}{v_{n-1}},$$

and p + a = 0 is the equation of an asymptote. For, since

$$u_{n} = p \cdot v_{n-1} u_{n-1} = a \cdot v_{n-1} + p \cdot v_{n-2}$$

it follows that

(4)
$$U_{n} \equiv (p + a) (v_{n-1} + v_{n-2}) + V_{n-2}$$

Therefore the line: p + a = o meets the curve: $U_n = o$ only when also $V_{n-2} = o$, that is, in but n-2 finite points. The remaining two points of intersection are accordingly at infinity, and p + a = o is an asymptote.

II. Parabolic Asymptotes. Suppose u_n contain a square factor, say

(5)
$$u_n = p^2 \cdot v_{n-2}$$

Then, applying the method of partial fractions.

(6)
$$\frac{u_{n-1}}{u_n} = \frac{q^1}{p^3} + \frac{v_{n-3}}{v_{n-2}},$$

where q is a linear homogeneous expression, and the parabola: $p^2 + q = o$ is asymptotic to the curve. For, since

$$u_{n} = p^{2} \cdot v_{n-2}$$

$$u_{n-1} = q \cdot v_{n-2} + p^{2} \cdot v_{n-3},$$

it follows that

(7)
$$U_n \equiv (p^3 + q) (v_{n-2} + v_{n-3}) + V_{n-3}$$

The parabola: $p^2 + q = o$ meets $U_n = o$ only when $V_{n-2} = o$, that is, in 2 (n-2) points. The remaining four points of intersection are at infinity. But any parabola of

27

the family

$$p^2+q+k=o,$$

where k is any constant, has the same property. For we can easily transmute (7) into the form

$$U_{\rm n} \equiv (p^2 + q + k) (v_{\rm n-2} + v_{\rm n-3}) + W_{\rm n-2},$$

and the same analysis holds.

There is therefore a family of asymptotic parabolas, meeting $U_n = o$ in four coincident points at infinity. If, however, k be so chosen that one of the intersections of $p^2 + q + k = o$ with $W_{n-2} = o$ be also at infinity, the parabola in question will have 5-point contact, or will osculate $U_n = o$. The necessary and sufficient condition for this osculation is that the axis of the parabola (p = o) should meet V_{n-2} at infinity, that is, that the terms of highest degree in V_{n-2} should contain p as a factor. The value of k in question can be determined by resolving

(8)
$$\frac{u_{n-2} - q \cdot v_{n-3}}{\not p \cdot v_{n-2}} = \frac{k}{\not p} + \frac{w_{n-3}}{v_{n-2}}$$

For in this case

$$u_{n-2} = k \cdot v_{n-2} + q \cdot v_{n-3} + p \cdot w_{n-3},$$

and hence

(9)
$$U_n \equiv (p^2 + q + k) (v_{n-3} + v_{n-3}) + p \cdot w_{n-3} + V_{n-3}$$

The parabola thus determined will then be regarded as the asymptote. This distinction is not made, so far as I have been able to discover, except by Plücker and Stolz in the memoirs referred to.

In particular, if q is a multiple of p, say $q = \mu p$, we have the case of parallel asymptotes. The given curve has a double point at infinity on the line: p = o, and the tangents at this double point, or the asymptotes, are given by the equation:

$$p^2 + \mu p + k = 0.$$

III. Cubic Asymptotes. Suppose u_n contain a cubic factor, say

(10)
$$u_n = p^3 \cdot v_{n-3}$$
.

Then, proceeding as before,

(II)
$$\frac{u_{n-1}}{u_n} = \frac{v_2}{p^3} + \frac{v_{n-4}}{v_{n-3}}.$$

Every cubic curve: $p^3 + v_2 + q + k = o$, where q is an arbitrary linear function and k an arbitrary constant, will meet the given curve in six points at infinity. But if q be determined by the resolution of

(12)
$$\frac{u_{n-2}-v_2 \cdot v_{n-4}}{p^2 \cdot v_{n-3}} = \frac{q}{p^2} + \frac{w_{n-4}}{v_{n-3}},$$

then every such cubic curve, where k alone is arbitrary, will meet the given curve in *eight* coincident points at infinity. For we shall have

$$\begin{array}{l} u_{\rm n} = p^3. \ v_{\rm n-3} \\ u_{\rm n-1} = v_2 \ . \ v_{\rm n-3} + p^3. \ v_{\rm n-4} \\ u_{\rm n-2} = q \ . \ v_{\rm n-3} + v_2 \ . \ v_{\rm n-4} + p^3. \ w_{\rm n-4} \end{array}$$

and consequently

(13)
$$U_n \equiv (p^3 + v_2 + q + k)(v_{n-3} + v_{n-4}) + p^2 \cdot w_{n-4} + V_{n-3}$$

There will in general be no particular one of this family of cubics having closer than 8-point contact with the given curve. But if v_2 contain p, say $v_2 = p \cdot r$, there is 9-point contact with all cubics of the family, and there will be one member of the family having 10-point contact, namely that one for which k is determined by the resolution of

(14)
$$\frac{u_{n-3}-q \cdot v_{n-4}}{\not p \cdot v_{n-3}} = \frac{k}{\not p} + \frac{w'_{n-4}}{v_{n-3}}.$$

For then we shall find that

(15)
$$U_{n} \equiv (p^{3} + p r + q + k) (v_{n-3} + v_{n-4}) + p^{2} \cdot w_{n-4} + p \cdot w'_{n-4} + V_{n-4}.$$

The extension of the method to higher cases is so obvious that I will not carry it further, especially since the number of special cases to be considered soon becomes inconveniently large, and it does not seem worth while to discuss them.

SYSTEMS OF SIMPLE GROUPS DERIVED FROM THE ORTHOGONAL GROUP.

(Second Paper.)

BY LEONARD EUGENE DICKSON, PH. D.

Instructor in Mathematics, University of California.

1. This paper completes the investigations begun in the Proceedings of the California Academy of Sciences, 3d Ser., Math.-Physics, Vol. I, No. 4, pp. 29-46. The final result may be stated as follows:—

The squares of the linear substitutions on m indices in the Galois Field of order p^n , p>2, which leave the sum of the squares of the m indices invariant, generate a group which is simple if m be odd (with the exception $p^n=3$, m=3), but has the factors of composition 2 and one-half its order if m be even and >4.

2. The case $p^n = 8 l \pm 1$ remains to be treated. Let $O_{1, 2}^{x, \beta}$ denote a particular substitution not in the group $Q_{1,2}$. We study the group H_1 given by extending Q_1 by all the products $O_{i,j}^{x,\beta} Q_{k,l}^{x,\beta}$.

Theorem. H_1 contains half of the substitutions of G, the group of all orthogonal substitutions of determinant unity. In fact, every substitution of G is of the form

$$h_1 O_{i,j}^{x,\beta}$$
 $h_2 O_{k,l}^{x,\beta}$ h_3,\ldots

 h_1, h_2, \ldots being substitutions of H_1 . This product can be put into the form h $O_{1,2}^{x,\beta}$. Indeed, $O_{i,j}^{x,\beta}$ can be carried to the right of every $Q_{i,j}^{\lambda,\mu}$ and every $Q_{k,l}^{\lambda,\mu}$ (k and $l \leq i,j$).

¹ For p = 17 this extension is unnecessary [see appendix].

² Compare § 8.

Since
$$\left(O_{i,k}^{x,\beta}\right)^2 = Q_{i,k}^{x,-\beta}$$
, we have
$$O_{i,j}^{x,\beta} Q_{i,k}^{\lambda,\mu} = O_{i,j}^{x,\beta} \left(O_{i,k}^{x,\beta}\right)^2 Q_{i,k}^{x,\beta} \bullet Q_{i,k}^{\lambda,\mu}$$
$$= O_{i,j}^{x,\beta} O_{i,k}^{x,\beta} \bullet Q_{i,k}^{x,\beta} Q_{i,k}^{\lambda,\mu} \bullet O_{i,k}^{x,\beta} = h' O_{i,k}^{x,\beta}$$

Our product will finally take the form

$$h'' O_{r,s}^{x,\beta} = h'' O_{r,s}^{x,\beta} O_{2,1}^{x,\beta} \bullet O_{1,2}^{x,\beta} = h O_{1,2}^{x,\beta}.$$

3. Theorem. For m>4 the maximal invariant subgroup I of H_1 is of order 1 or 2 according as m is odd or even.

The proof is quite similar to that given for the case $p^n = 8l \pm 3$ in the paper cited. The lemma of § 6 is now replaced by the following

Lemma. If I contains C, C, it coincides with H1.

Thus
$$O_{2,4}^{\kappa,\beta}$$
 $O_{1,2}^{\kappa,\beta}$ transforms C_1 C_3 into $Q_{1,2}^{\kappa,\beta}$ C_1 C_3 .

Hence I contains every $Q_{i,j}^{x,\beta}$ and in particular T_{23} C_{3} (2 being a square). Thus I contains

$$(T_{23} C_3) (O_{12} O_{14}) (T_{23} C_3)^{-1} (O_{12} O_{14})^{-1} = O_{13} O_{21}.$$

 $(T_{23} C_3 T_{14} C_4) (O_{12} O_{14}) (T_{23} C_3 T_{14} C_4)^{-1} (O_{12} O_{14})^{-1} = O_{43} O_{21}.$

In §10 replace O_{1345} T_{12} C_1 by O_{1345} $O_{1,2}^{x,\beta}$. The development at the end of § 18 is unnecessary when 2 is a square. Thus from

$$\rho_1^2 + \rho_2^2 + \rho_3^2 = 0$$
, $\rho_1^2 + \rho_2^2 = 2$,

it follows that $\rho_3^2 = -2$; while -1 was supposed to be a not-square.

4. Under the subdivision $p^n = 8 / \pm 3$, the cases $p^n = 3$ and 5 were excluded in the earlier paper.

Consider the case $p^n = 5$, m > 4. [See p. 41 of paper cited.] $T_{12} C_1$ extends H to the total group G; indeed, it transforms R into $C_2 C_3 R T_{12} T_{13} C_2 C_3$, viz.:

$$\begin{pmatrix} 2 & -\mathbf{I} & -\mathbf{I} \\ -\mathbf{I} & \mathbf{I} & 2 \\ -\mathbf{I} & 2 & \mathbf{I} \end{pmatrix} = R^{-1} C_1 C_2 R.$$

The variations from the proof of the theorem of § 4 of my paper, necessary for the case $p^a = 5$, are the following. Instead of applying the lemma in § 6 (which becomes trivial for $p^a = 5$), we note that the transformed of C_1 C_2 by R is not a product of the C_1 (as shown by the above formula). We may omit § 11. For p. 36 we note that the value $p^2 = 1$ may be chosen, the right member of the equation of condition being then zero. At the end of § 14, when $x \cdot \beta = 0$, I contains C_1 C_2 and thus, by the above formula, also the substitution

$$R T_{12} T_{13} = \left(\begin{array}{ccc} 2 & I & I \\ I & I & 2 \\ I & 2 & I \end{array} \right) = S_{\sigma} T_{23},$$

if we take $\sigma_1 = \sigma_2 = \sigma_3 = \pm 2$, so that

$$I - \sigma_i^2 = 2$$
, $- \sigma_i \sigma_j = I$.

5. We pass next to the case $p^n = 3$.

For m = 3, the group H is the composite group

$$G_{12} = \left\{ \text{ I, } C_{1} C_{j} \text{ (three), } T_{ij} T_{ik} \text{ (two), } T_{ij} T_{ik} C_{t} C_{l} \text{ (six)} \right\}.$$

For m>3, the total group G may be generated by the C_1 C_1 and T_{ij} C_k together with the substitution of determinant +1:

$$W = \begin{pmatrix} 1 & 2 & 2 & 2 \\ 1 & 2 & 1 & 1 \\ 1 & 1 & 2 & 1 \\ 1 & 1 & 1 & 2 \end{pmatrix}, \quad W^2 = W^{-1} = C_1 \ WC_1.$$

The C_i C_j generate a group of order

$$2^{m-1} = I + \frac{m(m-1)}{1 \cdot 2} + \frac{m(m-1)(m-2)(m-3)}{1 \cdot 2 \cdot 3 \cdot 4} + \cdots,$$

[&]quot;In the theoram given on p. 30 of my earlier paper, $p^n \ge 5$ should read $p^n > 5$. The case $p^n = 3$ was not observed to be special until it was noticed that in Jordan, $\sqrt[6]{211}$, case 2^0 is proved only when -1 is a not-square. The case 3^n , n > 1, can be readily disposed of.

which the alternating group on m letters extends to a group H' of order $\frac{1}{2}m$! 2^{m-1} . This group is extended by W to our group H of index 2 under G. Indeed T_{12} C_1 transforms W into W^2 C_1 C_2 , so that T_{12} C_1 will extend H to G.

For m=4, the left-hand multipliers in a rectangular table for H (of order 2^5 . 3^2) with H' (of order 2^5 . 3) as first row may be taken to be 1, W, W^2 . Indeed, we have

$$T_{13}$$
 T_{12} $W = W$ T_{13} T_{12} C_1 C_3 , C_1 C_2 $W = W$ T_{12} T_{34} C_1 C_2 C_3 C_4 .

The factors of composition of H are thus 3, 3, 2, 2, 2, 2, 2.

6. Theorem. For m>4, $p^n=3$, the maximal invariant sub-group I of H is of order 1 or 2 according as m is odd or even.

If I contains a substitution different from $C_1 C_2 \ldots C_m$ but commutative with every $C_1 C_1$, it will contain $C_1 C_5$ (by § 5 of the earlier paper) and hence also

$$W^{-1} C_1 C_5 W = W^{-2} C_1 C_5 = W C_1 C_5$$

which is not commutative with every C_i , C_j .

Applying § § 6, 9, 10 and the first of § 11, we find that I contains S' which leaves ξ_8 , ... ξ_m fixed and has $\beta_{51} = \beta_{51} = \beta_{71} = 0$. Of the three quantities β_{52} , β_{52} , β_{73} , two may be chosen, say β_{52} and β_{62} , such that both are zero or both not zero (viz., \pm 1). Transforming by C_1 C_5 , if necessary, we may assume that $\beta_{52} = \beta_{62}$. Thus our substitution is commutative with T_{56} . If commutative with every T_{1j} it becomes [see p. 36]:

$$\xi'_{1} = -\xi_{1} + 2(\xi_{1} + ... + \xi_{7})$$
 $(i = 1...7)$.

Its transformed by C_1 C_2 is not of this form. Hence I contains a substitution S commutative with T_{56} but not with T_{12} for example. Thus [see top of p. 37] I contains a substitution leaving ξ_6 and ξ_7 fixed. We are thus led to the case of a substitution affecting only 5 indices:

$$S: \xi_i = \sum_{j=1}^5 x_{ij} \xi_j \quad (i=1..5),$$

which is not a mere product of the C_1 C_1 . Thus, if every $x_{11} \ge o$, must $x_{12} \ge o$, for example. Hence S is not

commutative with C_1 C_2 ; for we can not have $x_{11}^2 + x_{12}^2 = 1$ as required by the note to p. 32. Thus I contains S^{-1} C_1 C_2 S C_2 C_1 , not the identity and having the coefficient

$$x_{11}' = -(1-2 x_{11}^2 - 2 x_{12}^2) \equiv 0 \pmod{3},$$

We may therefore suppose that $x_{11} = o$ in the substitution S. Transforming by O_{5432} we may make a second coefficient $x_{1j} = o$. Then from

$$\sum_{j=1}^{5} x_{1j}^{2} \equiv 1 \pmod{3}$$

it follows that four of the x_{1j} 's are zero. Let $x_{15} \geq o$. Thus S is not commutative with C_5 so that I contains R_x C_1 C_5 not the identity (p. 40). Four of the x_{2j} 's are all zero or all not zero. Transforming by certain C_5 C_1 , when necessary, we may suppose that, for example,

$$x_{21} = x_{22} = x_{23}$$
, $x_{11} = x_{12} = x_{13} = 0$.

Hence R_x C_1 C_5 is commutative with T_{12} T_{13} . Hence I contains the substitutions

$$(C_1 C_5 R_{\mathcal{X}}) T_{13} T_{12} (R_{\mathcal{X}} C_1 C_5) T_{12} T_{13} = C_1 C_5 \bullet C_2 C_5 = C_1 C_2,$$

$$W^{-1} C_1 C_5 W C_1 C_5 = W, T_{12} T_{34} = W^{-1} C_1 C_2 W C_1 C_2 C_3 C_4.$$

Hence I coincides with H.

7. Theorem. The Orthogonal Group on 3 indices in the G F $[p^n]$, p>2, has a sub-group H of order $\frac{1}{2}$ p^n $(p^{2n}-1)$ which is simply isomorphic to the group of linear fractional substitutions of determinant unity on one index.

Let *i* be a root, real or imaginary, of $i^2 = -1$; so that *i* belongs to our $G F [p^n]$ only when -1 =square.

Introduce in place of ξ_1 , ξ_2 , ξ_3 the new indices

$$\eta_1 = -i \xi_1$$
, $\eta_2 = \xi_2 - i \xi_3$, $\eta_3 = \xi_2 + i \xi_3$,
whence $-\eta_1^2 + \eta_2 \eta_3 = \xi_1^2 + \xi_2^2 + \xi_3^2$.

The orthogonal substitution

$$S: \xi_i = \sum_{i=1}^3 x_{ij} \xi_i \quad (i = 1, 2, 3)$$

takes the form S_1 :

$$\begin{split} \eta_{1}' &= x_{11} \, \eta_{1} + \frac{1}{2} \, \left(x_{13} - i \, x_{12} \right) \, \eta_{2} - \frac{1}{2} \, \left(x_{13} + i \, x_{12} \right) \, \eta_{3}, \\ \eta_{2}' &= \left(x_{31} + i \, x_{31} \right) \, \eta_{1} + \frac{1}{2} \, \left(x_{32} - i \, x_{32} + i \, x_{23} + x_{33} \right) \, \eta_{2} + \\ \frac{1}{2} \, \left(x_{22} - i \, x_{33} - i \, x_{23} - x_{33} \right) \, \eta_{3} \, , \\ \eta_{3}' &= \left(-x_{31} + i \, x_{31} \right) \, \eta_{1} + \frac{1}{2} \, \left(x_{22} + i \, x_{32} + i \, x_{23} - x_{33} \right) \, \eta_{2} + \\ \frac{1}{2} \, \left(x_{22} + i \, x_{32} - i \, x_{23} + x_{33} \right) \, \eta_{3} \, . \end{split}$$

It is proven below that the coefficient

$$\frac{1}{2}(x_{33}+x_{33})+i/2(x_{23}-x_{33})=x^2$$

x being a complex of the form $\rho + \sigma i$, where ρ and σ are marks of the $G F [p^n]$. It follows that the coefficient of η_3 in η_2 is a square, viz.:

$$\frac{1}{2}(x_{22}-x_{33})-i/2(x_{23}+x_{32})=\beta^2.$$

In fact, by virtue of the orthogonal relations (2), p. 30,

$$x^{2} \beta^{2} = \frac{1}{4} (x_{22}^{2} + x_{23}^{2} - x_{32}^{2} - x_{33}^{2}) - i/4 (2 x_{22} x_{32} + 2 x_{23} x_{33})$$
$$= \frac{1}{4} (x_{31} + i x_{31})^{2}.$$

The coefficients of η_2 and η_3 in η_3 are squares, say γ^2 and δ^2 , since they are the conjugates of β^2 and x^2 respectively. We may verify that

$$x^2 \gamma^2 = \frac{1}{4} (x_{18} - i x_{12})^2$$

whose conjugate is therefore β^2 δ^2 . Further, we find 1

$$\left|\begin{array}{cc} x^2 & \beta^2 \\ \gamma^2 & \delta^2 \end{array}\right| = x_{22} x_{33} - x_{32} x_{23} - x_{11}.$$

Also $(x \delta + \beta \gamma)^2$ when expanded reduced to x_{11}^2 .

Hence

$$x \delta - \beta \gamma = 1$$
.

Our substitution S_1 thus becomes ²

$$\begin{pmatrix} x \ \delta + \beta \ \gamma & x \ \gamma & \beta \ \delta \\ 2 \ x \ \beta & x^2 & \beta^2 \\ 2 \ \gamma & \delta & \gamma^2 & \delta^2 \end{pmatrix} \quad [x \ \delta - \beta \ \gamma = 1].$$

Giving S_1 the notation $\begin{bmatrix} x & \beta \\ \gamma & \delta \end{bmatrix}$ we verify the composition formula for $S_1' S_1$:

¹ Baltzer, Determinanten, § 14, 5, page 189.

² Compare Fricke-Klein, Automorphe Functionen, I, p. 14; also Weber, Algebra, II, p. 190.

$$\begin{bmatrix} x' & \beta' \\ \gamma' & \delta' \end{bmatrix} \begin{bmatrix} x & \beta \\ \gamma & \delta \end{bmatrix} = \begin{bmatrix} x & x' + \beta & \gamma' & x & \beta' + \beta & \delta' \\ \gamma & x' + \delta & \gamma' & \gamma & \beta' + \delta & \delta' \end{bmatrix}.$$

Thus if $\frac{1}{2}(x_{22} + x_{33}) + i/2(x_{23} - x_{22})$, which is one of the coefficients in S_1 , be a square x^2 , and if the corresponding coefficient in S_1 be a square x^2 , then will that of S_1 be the square $(x x' + \beta \gamma')^2$.

For the substitution $O_{2,3}^{\lambda,\mu}$ the above expression is

$$\lambda + i \mu = (\rho + i \sigma)^2$$

if
$$\lambda = \rho^2 - \sigma^2$$
, $\mu = 2 \rho \sigma$, i. e., if $O_{2,3}^{\lambda,\mu} = Q_{2,3}^{\rho,\sigma}$.

For $O_{1,2}^{\lambda,\mu}$, the expression is $\frac{1}{2}(\lambda + 1) = \rho^2$ if $O_{1,2}^{\lambda,\mu} =$

$$Q_{1,2}^{\rho,\sigma}$$
.

For $O_{1,2}^{\lambda,\mu}$ $O_{1,3}^{\lambda,\mu}$ the expression is

$$\frac{1}{2}(2 \lambda + i \mu^2) = \left\{ \frac{1}{2}(1 + i)(1 - i \lambda) \right\}^2.$$

For $O_{1,2}^{\lambda,\mu}$ $O_{3,1}^{\lambda,\mu}$, it is the conjugate of the latter. For the

special case
$$O_{1,3}^{0,-1}$$
 $O_{3,1}^{0,-1} = T_{12}$ T_{18} it is $\frac{-i}{2} = \left(\frac{1-i}{2}\right)^2$.

For the generator R (necessary when $p^n = 5$) it is 3^2 . Since the group H can be generated from the above substitutions, it follows that our expression is always a square.

We have therefore proven that H is simply isomorphic to the group Γ of linear fractional substitutions of determinant unity on one index. When $-\mathbf{1}$ is a square, the coefficients x, β , γ , δ belong to the $GF[p^n]$ and, if $p^n > 3$, the group Γ is simple. When $-\mathbf{1}$ is a not-square, the coefficients

¹ A direct proof by induction could doubtless be made. Thus the expression, denoted by x^2 for the substitution S_1 , when built for the product $O_{2,3}^{\lambda,\mu} S_1$ is seen to be $(\lambda + i \mu) x^2$.

² Moore, A doubly-infinite system of simple groups, Mathematical Papers of the Chicago Congress of 1893. Other proofs have since been given by Burnside and Dickson.

- x, δ and also β , γ are conjugate imaginaries in i, so that Γ is the "imaginary form" of the former simple group. Hence the ternary orthogonal group H is simple if $p^n > 3$.
- 8. It follows from what precedes that for m=3 the sub-group H does not coincide with the total group G, but is of index 2 under it. A similar result doubtless holds for any m. To prove that our group H is generated by the squares of the substitutions of G (as stated in § 1), we note that

$$\left(O_{1,2}^{x,-\beta}\right)^2 = Q_{1,2}^{x,\beta}, \left(O_{1,2}^{x,\beta} T_{18} T_{24}\right)^2 = O_{1,2}^{x,\beta} O_{3,4}^{x,\beta}$$

$$\left(O_{1,2}^{x,\beta} T_{18} C_1 C_2 C_3\right)^2 = O_{1,2}^{x,\beta} O_{3,2}^{x,\beta}.$$

The orders of the simple groups reached are as follows:

For
$$m = 2 k + 1 = 3$$
, $p > 2$, and $p^n > 3$ when $m = 3$, $\frac{1}{2} (p^{2nk-1}) p^{2nk-n} (p^{2nk-2n}-1) p^{2nk-3n} \dots (p^{2n}-1) p^n$; for $m = 2 k > 4$,

APPENDIX.

9. For $p^n = 7$, m = 3, the Q_{ij} constitute the group G_{24} of page 44. This is extended by $O_{1,2}^{2,2}$ to the group of all 14.24 orthogonal substitutions of determinant +1. For a rectangular table of the latter with G_{24} as first line we may choose as left hand multipliers

$$egin{aligned} & {
m i} \ , \ O_{18} \ O_{28} \ , \ O_{28} \ O_{12} \ , \ O_{28} \ O_{18} \ , \ & O_{12} \ O_{18} = \left(egin{array}{ccc} 4 & 4 & 2 \ -2 & 2 & 0 \ -4 & -4 & 2 \end{array}
ight) \ , \ O_{18} \ O_{12} = \left(egin{array}{cccc} 4 & 2 & 4 \ -4 & 2 & -4 \ -2 & 0 & 2 \end{array}
ight) \ , \ & O_{12} \ O_{23} = \left(egin{array}{cccc} 2 & 2 & 0 \ -4 & 4 & 2 \ 4 & -4 & 2 \end{array}
ight) \ , \end{array}$$

¹ Moore, 1. c. § 6.

$$O_{12} , O_{18} , O_{28} , O_{13} O_{12} O_{28} = \begin{pmatrix} 4 & 2 & 4 \\ 2 & 4 & -4 \\ 4 & -4 & -2 \end{pmatrix},$$

$$O_{23} O_{12} O_{13} = \begin{pmatrix} 4 & 4 & -2 \\ -2 & 4 & 4 \\ -4 & 2 & -4 \end{pmatrix}, O_{23} O_{12} O_{23} = \begin{pmatrix} 2 & 4 & 4 \\ -4 & 4 & -2 \\ 4 & 2 & -4 \end{pmatrix},$$

$$O_{13} O_{23} O_{13} = \begin{pmatrix} -4 & -4 & -2 \\ -4 & 2 & 4 \\ 2 & -4 & 4 \end{pmatrix}.$$

It may be verified that the whole group has been reached. Thus, for example,

$$O_{13} \ O_{12} \ O_{13} = O_{28} \ O_{12} \ O_{18} \ T_{28} \ C_{2},$$
 $O_{23} \ O_{13} \ O_{12} = O_{18} \ O_{12} \ O_{23} \ T_{12} \ T_{18} \ C_{2} \ C_{8},$
 $\left(O_{18} \ O_{12}\right)^{2} = O_{28} \ O_{12} \ T_{12} \ T_{18} \ C_{2} \ C_{8},$
 $O_{13} \ O_{12} \bullet O_{28} \ O_{13} = O_{28} \ O_{13} \ T_{28} \ C_{3} \ ,$
 $O_{13} \ O_{12} \bullet O_{28} \ O_{12} = O_{12} \ O_{28} \ T_{23} \ C_{1} \ C_{2} \ C_{8}.$

Our subgroup H of index 2 is obtained by taking only the seven multipliers in the first three lines.

10. For $p^n = 9$, m = 3, the Q_{ij} constitute the same G_{24} . Define the $G F [3^2]$ by the congruence $i^2 \equiv -1 \pmod{3}$. Then $O_{1,2}^{i,1}$ extends G_{24} to the total group $G_{30,24}$, for a rectangular table of which with G_{24} as first line we may choose the left hand multipliers

$$\begin{array}{c} \text{I} \;\; , \;\; O_{1,2}^{i,i} \;\; , \;\; O_{1,3}^{i,i} \;\; , \;\; O_{2,3}^{i,i} \;\; , \\ O_{12} \;\; O_{13} = \begin{pmatrix} -\mathrm{I} & -\mathrm{I} & i \\ -i & i & 0 \\ \mathrm{I} & \mathrm{I} & i \end{pmatrix} \;\; , \;\; O_{23} \;\; O_{12} \;\; O_{18} = \begin{pmatrix} -\mathrm{I} \;\; \mathrm{I} - i & -\mathrm{I} - i \\ -i & -\mathrm{I} & -\mathrm{I} \\ \mathrm{I} \;\; \mathrm{I} + i & -\mathrm{I} + i \end{pmatrix} \;\; , \\ (O_{12} \;\; O_{18})^2 = \begin{pmatrix} \mathrm{I} - i & \mathrm{I} & -\mathrm{I} - i \\ \mathrm{I} + i & -\mathrm{I} + i & \mathrm{I} \\ -\mathrm{I} & -\mathrm{I} - i & -\mathrm{I} + i \end{pmatrix} \;\; , \;\; (O_{23} \;\; O_{12} \;\; O_{18})^2 = \\ \begin{pmatrix} -\mathrm{I} + i & \mathrm{I} & -\mathrm{I} - i \\ -\mathrm{I} - i & -\mathrm{I} + i & \mathrm{I} \\ -\mathrm{I} & -\mathrm{I} + i & \mathrm{I} - i \end{pmatrix} \;\; , \end{array}$$

there being six with a single element o, twelve with a single

element $\pm i$, and eight with neither o nor $\pm i$. The 15 multipliers giving our simple group H are those with an even number of the O_{ij} .

II. For $p^n = 17$, the Q_{ij} are $C_i C_j$, $T_{ij} C_i$ or $O_{ij}^{\pm 3}$.

$$S \equiv O_{1,3}^{3,3} O_{1,3}^{3,3} = \begin{pmatrix} 9 & 9 & 3 \\ -3 & 3 & 0 \\ -9 & -9 & 3 \end{pmatrix} , S^{2} = \begin{pmatrix} -7 & -4 & 2 \\ -2 & -1 & -9 \\ 4 & 1 & -1 \end{pmatrix}$$

$$S^4 = O_{31}^{23} T_{23} C_1 C_2 C_3$$
, $S^8 = S^{-1}$, $S^9 = 1$.

$$O_{1,3}^{6,4}O_{1,3}^{6,4} = \begin{pmatrix} 2 & 7 & 4 \\ -4 & 6 & 0 \\ -7 & 1 & 6 \end{pmatrix} = \begin{pmatrix} 2 & 7 & 4 \\ 1 & 4 & 1 \\ -9 & 2 & 1 \end{pmatrix} \bullet O_{3,3}^{3,3}$$

$$=T_{13} T_{12} C_1 C_2 (O_{13}^{33} O_{13}^{33})^2 T_{23} C_2 \bullet O_{33}^{33}.$$

Also, the square of $O_{1,2}^{6,4}$ gives $O_{1,2}^{6,-3}$. Hence the product of any two of the $O_{1,2}^{4,6,4}$ belongs to Q.

Note that $T \equiv O_{11}^{33} O_{12}^{33} O_{13}^{33}$ is of period six; thus,

$$T = \begin{pmatrix} 9 & 1 & 2 \\ -3 & 9 & 9 \\ -9 & -2 & -1 \end{pmatrix}, T^{2} = \begin{pmatrix} -8 & -3 & 8 \\ 1 & -8 & -2 \\ 2 & -8 & -1 \end{pmatrix}, T^{4} = T^{-1}.$$

12. Theorem. There exists in the group Q_{12} a substitution of the form $O_{1,2}^{\lambda,\lambda}$ if and only if $p^n = 16 l \pm 1$.

Since 2 must be a square $(2 \lambda^2 = 1)$ the group Q_{12} has the subgroup $\{1, C_1, C_2, T_{12}, C_1, T_{12}, C_2\}$. Multiplying on the left by $O_{1,2}^{x,\beta}$ we reach

$$O_{1,2}^{x,\beta}$$
, $O_{1,2}^{-x,-\beta}$, $O_{1,2}^{\beta,-x}$, $O_{1,2}^{-\beta,x}$.

Similarly the multiplier $O_{1,2}^{x,-\beta}$ gives a set of four, different from the former only when β differs from $\pm x$. Hence there are 8k or 8k+4 distinct substitutions in Q_{12} , according as $O_{1,2}^{\lambda,\lambda}$ occurs or not. The order of the group

being $\frac{1}{2}(p^n-\epsilon)$, where $\epsilon=\pm 1$ according as $p^n=4$ $t\pm 1$, the condition for $O_{1,2}^{\lambda,\lambda}$ is that $p^n-\epsilon$ be divisible by 16.

Since the condition that $O_{1,2}^{x,\beta}$ be a $Q_{1,2}$ is that $2 (1 \pm x)$ be squares, the condition that $O_{1,2}^{\lambda,\lambda}$ occur among the $Q_{1,2}$ is that $2 \pm \sqrt{2}$ be squares.

Corollary. $2+\sqrt{2}$ is a square in the $G F [p^n]$ only when p^n is of the form $16 l \pm 1$.

Thus for
$$p^n = 17$$
, $\lambda = 3$, $2 + \sqrt{2} \equiv 2 + 6 \equiv 5^2$ (mod. 17);
for $p^n = 31$, $\lambda = 4$, $2 + \sqrt{2} \equiv 2 + 8 \equiv 14^2$ (mod. 31).

•

ON AN m n² PARAMETER GROUP OF LINEAR SUBSTITUTIONS IN m n VARIABLES.

BY E. J. WILCZYNSKI, PH. D.,

Instructor in Mathematics, University of California.

§ 1. All substitutions of the form

$$\begin{cases}
\eta_{i} = \sum_{k=1}^{n} a_{ik} y_{k} \\
\eta_{i}^{(1)} = \sum_{k=1}^{n} (a_{ik}' y_{k} + a_{ik} y_{k}') \\
\eta_{i}^{(2)} = \sum_{k=1}^{n} (a_{ik}'' y_{k} + a_{ik}' y_{k}' + a_{ik} y_{k}'') \\
\dots \\
\eta_{i}^{(m-1)} = \sum_{k=1}^{n} (a_{ik}^{(m-1)} y_{k} + a_{ik}^{(m-2)} y_{k}' + \dots + a_{ik} y_{k}^{(m-1)}) \\
(i = 1, 2, \dots n)
\end{cases}$$

belong to a group G. There are m n variables and $m n^2$ parameters. If D denotes the determinant

$$D = |a_{ik}|, (i, k = 1, 2, ... n)$$

then the determinant of (1) is D^{m} .

The m n^2 independent infinitesimal transformations of

$$\begin{cases} U_{ik}^{(0)} f = \frac{\mathrm{d}f}{\mathrm{d}y_{i}} \ y_{k} + \frac{\mathrm{d}f}{\mathrm{d}y_{i}'} \ y_{k'} + \dots + \frac{\mathrm{d}f}{\mathrm{d}y_{i}^{(m-1)}} \ y_{k}^{(m-1)} = \\ \sum_{\lambda=0}^{m-1} \frac{\mathrm{d}f}{\mathrm{d}y_{i}^{(\lambda)}} \ y_{k}^{(\lambda)} \end{cases}$$

$$U_{ik}^{(1)} f = \frac{\mathrm{d}f}{\mathrm{d}y_{i}} \ y_{k} + \dots + \frac{\mathrm{d}f}{\mathrm{d}y_{i}^{(m-1)}} \ y_{k}^{(m-2)} = \\ \sum_{\lambda=1}^{m-1} \frac{\mathrm{d}f}{\mathrm{d}y_{i}^{(\lambda)}} \ y_{k}^{(\lambda-1)}$$

$$U_{ik}^{(m-2)} f = \frac{\mathrm{d}f}{\mathrm{d}y_{i}} \ y_{k}^{(m-2)} \ y_{k} + \frac{\mathrm{d}f}{\mathrm{d}y_{i}^{(m-1)}} \ y_{k'} = \sum_{\lambda=m-2}^{m-1} \frac{\mathrm{d}f}{\mathrm{d}y_{i}^{(\lambda)}} \ y_{k}^{(\lambda-(m-2))}$$

$$U_{ik}^{(m-1)} f = \frac{\mathrm{d}f}{\mathrm{d}y_{i}} \ y_{k}^{(m-1)} \ y_{k} \ ,$$

or in general

$$(2) \quad U_{ik}^{(\rho)} f = \sum_{\lambda=\rho}^{m-1} \frac{\mathrm{d}f}{\mathrm{d}y_i^{(\lambda)}} y_k^{(\lambda-\rho)} \begin{pmatrix} i, k=1, 2, \ldots n \\ \rho=1, 2, \ldots m \end{pmatrix}.$$

§ 2. Relations between the Symbols $U_{ik}^{(p)}f$.

If we wish to investigate questions as to the invariants of the group, we must know how many of the equations $U_{ik}^{(\rho)}f=o$ are independent. It is therefore necessary to find the relations between the different symbols. We find at once

i. e., $n(n-1) = n^2 - n$ relations. Therefore only n of the equations $U_{lk}^{(m-1)} f = 0$ are independent, and there are obviously not less than n.

Further we find

(4) $y_i U_{ik}^{(m-2)} f - y_k U_{ij}^{(m-2)} f = y_k' U_{ij}^{(m-1)} f - y_i' U_{ik}^{(m-1)} f$, again $n^2 - n$ relations, which show that just n of the equations $U_{ik}^{(m-2)} f = 0$ are independent.

Generally we have

(5)
$$y_{i} U_{ik}^{(\rho)} f - y_{k} U_{ij}^{(\rho)} f = \sum_{\lambda=\rho+1}^{m-1} \frac{\mathrm{d}f}{\mathrm{d}y_{i}^{(\lambda)}} \left(y_{k}^{(\lambda-\rho)} y_{j} - y_{i}^{(\lambda-\rho)} y_{k} \right),$$

where the right member can evidently be expressed in terms of $U_{ik}^{(\rho+1)} f$, .. $U_{ik}^{(m-1)} f$. Therefore, by induction, for every value of ρ there are precisely n equations of the form $U_{ik}^{(\rho)} f = o$ which are independent. Altogether, therefore, there are m n independent equations, which form a complete system in m n variables. This system therefore has no solution except f = const. The general group G therefore has no invariants, i. e., it is transitive.

§ 3. Composition of the Group. Commutator-relations. We have

(6)
$$U_{ik}^{(\rho)} f = \sum_{\lambda=\rho}^{m-1} \frac{\mathrm{d}f}{\mathrm{d}y_i^{(\lambda)}} y_k^{(\lambda-\rho)}$$

(7)
$$U_{\mathfrak{p}}^{(\sigma)} f = \sum_{\lambda=\sigma}^{m-1} \frac{\mathrm{d}f}{\mathrm{d}y_{\mathfrak{p}}(\lambda)} y_{\mathfrak{p}}^{(\lambda-\sigma)}$$
.

Now
$$U_{ik}^{(\rho)}\left(y_1^{(\lambda-\sigma)}\right) = o \text{ for } \lambda = \sigma, \dots m-1, \text{ if } \rho > m-1-\sigma,$$

and
$$U_{ij}^{(\sigma)}\left(y_{k}^{(\lambda-\rho)}\right)=o$$
 for $\lambda=\rho,\ldots m-1$, if $\sigma>m-1-\rho$.

Therefore

(8)
$$\left(U_{\mathbf{n}}^{(\rho)}, U_{\mathbf{n}}^{(\sigma)}\right) f = o$$

for $\rho + \sigma > m-1$.

So we have

It remains to consider those commutators, the sum of whose indices is not greater than m-1.

We find

(9)
$$\left(U_{ik}^{(\rho)}, U_{ji}^{(\sigma)}\right) f = 0$$

if $i \geq l$ and $j \geq k$.

Now let i = l, but $j \ge k$. Then

(10)
$$\left(U_{ik}^{(\rho)}, U_{ji}^{(\sigma)}\right) f = U_{jk}^{(\rho+\sigma)} f$$
, $(\rho+\sigma < m-1, j \ge k.)$
If $i = l$ and $j = k$,

(II)
$$\left(U_{ik}^{(\rho)}, U_{kl}^{(\sigma)}\right) f = U_{kk}^{(\rho+\sigma)} f - U_{ii}^{(\rho+\sigma)} f$$

$$(\rho + \sigma < m-1).$$

In particular, if i = k,

(12)
$$\left(U_{ii}^{(\rho)}, U_{ii}^{(\sigma)}\right) f = o.$$

Now let $i \ge l$ but j = k. Then we find in the same manner

(13)
$$\left(U_{ik}^{(\rho)}, U_{kl}^{(\sigma)}\right) f = -U_{il}^{(\rho+\sigma)} f$$
.

It is now easy to describe the structure of the group. The infinitesimal transformations $U_{ik}^{(\rho)} f$ for $\rho = 1, 2, ...$ m-1 generate a self-conjugate sub-group G_1 of G. For if we form $(U_{ik}^{(\rho)}, U_{il}^{(\sigma)})$ f, whenever it is not zero, it is found to be expressed in terms of $U_{\lambda\mu}^{(\rho+\sigma)} f$. Compounding therefore all of the infinitesimal transformations of G with those of G_1 , only operations of G_1 result. Therefore G_1 is a self-conjugate sub-group of G. It has $(m-1)n^2$ parameters. Similarly taking $U_{ik}^{(\rho)} f$ for $\rho = 2, 3 \dots m-1$, we find that these transformations generate a self-conjugate sub-group G_2 , with $(m-2)n^2$ parameters, of G_1 , and so on. We are thus finally led to an n^2 parameter group G_{m-1} which is self-conjugate sub-group of a 2 n² parameter group G_{m-2} , and which is generated by the infinitesimal transformations $U_{ik}^{(m-1)} f$. The finite equations of the group are

$$\eta_{i} = y_{i}, \quad \eta_{i}' = y_{i}', \quad \eta_{i}^{(m-1)} = y_{i}^{(m-2)},
\eta_{i}^{(m-1)} = a_{i1} y_{1} + a_{i2} y_{2} + \ldots + a_{in} y_{n} + y_{i}^{(m-1)}.
(i = 1, 2, \ldots n).$$

§ 4. Linear Differential Equations.

If the transformation group of a linear differential equation of the m n th order is the group G, it is easily seen that the integration of that equation can be reduced to the successive integration of the m equations of the n th order, out of which the equation of the m n th order is compounded, and quadratures. The same is true for the more general group which is found if in equations (1) the coefficient of $y_k(\lambda)$ in the expression for $\eta_i(\lambda)$ is arbitrary instead of being equal to a_{ik} . The group G however has a special significance owing to the fact that if η_1, \ldots, η_n and a_{ik} are considered as functions of a variable x, the group of linear substitutions

$$\eta_i = \sum_{k=1}^n a_{ik} y_k$$

extended m-1 times has the form of the group G.

Introduction.

This paper is prompted mainly by the many references made by astronomers and astronomical publications to "Baily's Beads" in cases of total solar eclipses; to the "black drop" and "ligament" in transits of Mercury and Venus over the Sun's disc; to the projection of a star upon the bright body of the Moon at immersion or emersion of occultation; to stars and the satellites of Jupiter seen through the limb or body of that planet at occultation; to planets surrounded by an atmosphere of great depth; and to empirical corrections to the semidiameters of the Sun and Moon at meridian transits.

We have lately examined the reports of the observers of the transits of Venus in 1874 and 1882; of the transits of Mercury since 1878, and the reports of the total solar eclipses since 1860; and we are amazed at the crude and apparently indigested explanations given for certain appearances attending the phenomena. There would seem to have been a desire to seek explanations in some obscure cause or causes—such as the poor character of the objective used, the lack of sharpness in the limbs of the planets (owing to their possessing an atmosphere), diffraction, telescopic and occular irradiation, astigmatism, "sympathetic attraction," etc.

These explanations are very unsatisfactory, and the experienced observer, who has observed occultations of stars by the Moon or by Jupiter, meridian transits of the Moon, transits of Mercury and Venus across the Sun's disc, and total solar eclipses in a serene atmosphere, knows that the outlines of the planets, the Moon, and the Sun are remarkably sharp and steady, even under high magnifying power; that the observations made under such conditions are satisfactory; and that there are no extraordinary phenomena present.

In such an atmosphere the spurious disc of a star, large or small, moves along the horizontal thread of the Meridian Circle, or the Zenith Telescope, so steadily that the error of observation should not exceed one-tenth of a second of arc. And the double-star observer certainly expects his measures of distance to differ little from that amount. In the telescope the diffraction rings of the stars are beautifully delicate. On a quiet night the stars appear, to the normal eye, fixed on the sky like minute dots of light, without a sign of twinkling or irradiation, and the intensity of the light of each star, large or small, is continuous.

The observer knows that in an atmosphere which is remarkably unsteady, when every star to the naked eye is dancing madly, the smallest stars have disappeared, the smaller ones appear and disappear spasmodically, and the larger ones near the horizon rapidly change color, and even the planets have much irradiation and are blinking; the star in the instrument has lost its diffraction rings, the spurious disc is broken up, and the confused mass jumps wildly across the micrometer thread and frequently expands into a nebulous film many seconds in diameter. We have measured such an apparition of Polaris forty-seven seconds in diameter.

"Burnham has remarked that an object-glass of six inches will one night show the companion of Sirius perfectly; on the next night, just as good in every respect, so far as one can tell with the unaided eye, the largest telescope in the world will show no more trace of the small star than if it had been blotted out of existence." (Webb's "Celestial Objects.")

With a serene atmosphere the transit observer is certain of his times. With a disturbed atmosphere he can make only an unsatisfactory estimate by eye and ear, and a still less reliable one by the chronograph.

In the course of fifty-four years' experience as an observer, largely in the field, we have encountered a range of physical conditions that falls to the lot of very few. We have made astronomical and geodetic observations in all climates, at all seasons, from the low ocean coast to elevations reaching 12,566 feet, and with instruments of precision of various character. Our latest astronomical observations

were made in perhaps the worst locality possible. The peninsula of San Francisco near the Golden Gate is unique for general unsteadiness of the atmosphere, yet marked on rare occasions by some supreme exhibitions of quietness.

GEODETIC OBSERVATIONS IN THE SIERRA NEVADA.

In the high Sierras of eastern California, from 7,250 to 10,430 feet elevation, after a great southeast storm with clearing weather in the night, a strong wind from the northwest, and a wonderfully pellucid sky and steady atmosphere to windward that gave astonishing clearness, sharpness, steadiness and apparent nearness to all objects, we have, at the greater elevation, seen star-like heliotrope images with the naked eye, at stations 120, 130, 140 and 160 miles distant to the west and northwest, whence the cold, keen wind was blowing. At this station, with the whole range covered with snow, the mountain face was precipitous for 1,356 feet to the north. To the southeastward and eastward, over the very deep valley of the Mokelumne River, directly under us, subject to the Sun's early warmth, the atmosphere became excessively disturbed and the heliotrope images in that direction were not visible to the eye at distances of forty miles. In the telescope the former images were steady, round, and so minute that the micrometer thread nearly covered them; the latter images were very diffuse, irregular and unsteady, and ranged from twenty seconds to thirty seconds in diameter. In the first case the pointing was quickly and satisfactorily made; in the second the pointings were unsatisfactory, even with half a dozen occular pointings as checks.

VISIBILITY OF JUPITER'S SATELLITES.

In astronomical work we have observed the Sun, Moon, planets and stars when the Sun was serenely steady; and at night not a star twinkled to the naked eye, and no irradiation was visible to Jupiter. Half a dozen times in our experience we have been able to distinguish with the naked

eye¹ two of Jupiter's satellites, when close together, as one; and at one mountain station (3,200 feet elevation) all the members of our party witnessed a similar phenomenon. Very curiously, that evening was slightly hazy, and very faint stars were not visible; but the atmosphere was remarkably steady. Under atmospheric condition of supreme quietness we have placed eleven stars in the Pleiades.

The visibility of Jupiter's satellites by the naked eye has generally been received with much doubt. Humboldt, in his Cosmos, has related a well authenticated case, but we can come to our own observers for confirmation. At the time of the total solar eclipse of August, 1878, one of the United States Naval Observatory observers in Colorado saw with the naked eye three satellites of Jupiter separately—two very distinctly and one less so. The atmosphere was supremely serene, and the station (Idaho Springs) 7,548 feet above the sea. Two other persons, not observers, also witnessed the phenomenon. In 1874 the Professor and his colleagues had doubted my seeing even two satellites close together as one.

Conditions of Steadiness and Unsteadiness of the Atmosphere.

Under similar atmospheric conditions the limbs of the Sun, Moon and planets are sharply defined and remarkably steady; the Sun-spots are beautifully distinct and their changes of form readily followed; the irregularities of the outline of the Moon are unmistakable; the spurious discs of the stars are encircled by delicate diffraction rings, and the overlapping spurious discs of very close double stars present new forms. Under conditions of supreme steadiness of the atmosphere, we believe that an observer with keen eyesight should see, with unassisted vision, the larger satellites of Jupiter, when favorably located, and from ten to twelve stars in the Pleiades. Either is a severe and unique test of steadiness and eyesight. In these periods of great steadiness the observer aches for finer micrometers, higher power, and more stable instruments.

¹ Except with spectacles for short-sightedness.

When the steadiness of the atmosphere begins to break, the images of the Sun, Moon and planets exhibit occasional tremors or shiverings; and even when this vibratory movement has become nearly continuous, but not rapid, the actual and apparently more condensed outline of the image can be selected for measures of precision in moments of quietude. As the unsteadiness of the atmosphere increases, the vibration of the limbs increases in rapidity and amplitude until there is finally created a blurred outline of Sun, Moon or planet, which necessarily presents an increased diameter of the object. The stars are similarly affected; with the first signs of unsteadiness in the atmosphere the diffraction rings are broken, and disappear as the unsteadiness increases; the spurious disc is broken into pieces; its march is peculiar, in presenting one fragment after another with more or less frequency, but may continue with a waltzing movement until the unsteadiness has increased and the spurious disc is without form, dilated, jumping wildly in every direction, and a wretched object for observation.

Similar conditions are exhibited by geodetic signals of all classes. In a serene atmosphere poles are seen very steady as fine, sharp images, sometimes finer than the micrometer threads. When this atmosphere is disturbed, tremors or shiverings carry the images to right or left one or more diameters, and the observer selects moments of quietude for first-class observations; finally, as the unsteadiness of the atmosphere increases, the images become large, confused, blurred and faint, and observations are difficult to make and unsatisfactory. In the quiet atmosphere, white poles five feet long and four and six-tenths inches in diameter, projected upon a dark background, have been seen with the naked eye at distances of four and one-half miles across water. In times of great unsteadiness and equally clear atmosphere they are difficult to see in the telescope.

Heliotrope images behave precisely as those of the stars. On a certain line of the main triangulation of the Pacific Coast, where plains, several mountain ridges and intervening valleys were crossed by the line of sight, and where

the cold ocean air sweeping through the Karquinez Strait added ten-fold confusion, the heliotrope image from Mt. Diablo, distant forty-five miles, was seen in the telescope like the waving flame from the stack of a smelting furnace. Sometimes the image exceeded sixty seconds in irregular diameter, and its horizontal direction was very abnormal. This condition lasted for many days. When the air became of more uniform temperature the image was small, starlike, and steady, and its direction normal.

In the remarkably quiet atmosphere of the mountains, before sunset, with a pure sky for a background, we once saw, with the two and one-eighth inches objective of the theodolite, the observer leave his station, which was thirty-three miles distant from Mt. Tamalpais. With a salmon-colored sky in the west, and the atmosphere remarkably clear and steady, Superintendent Bache observed upon the signal-pole of Mt. Wachusett, distant sixty-one miles. The image was nearly as dark and sharp as the cross-threads.

In winter, at great elevation, we once saw, with a threeinch objective, just after sunrise, with a serene atmosphere, the heliotroper projected against a snow background at a distance of fifty-one miles. From Mt. Diablo, 3,840 feet elevation, with the same size objective, just before sunrise, in a perfectly quiet atmosphere, when the crest-line of the Sierra Nevada was projected like a dark-blue saw against the warm eastern sky, and apparently only thirty or forty miles distant, we saw upon several mornings the observing hut on the pinnacle of Mt. Conness. The hut was six feet wide by seven and a half feet high, and the distance one hundred and forty-three miles; the width therefore sub-After the hut had been cut down to about tended 1".64. four feet we still made it out upon an extraordinarily clear and steady morning. On account of the distance and great height of Mt. Conness (12,566 feet) the Sun rose to the heliotroper about eight minutes earlier than to Mt. Diablo. The sharpness and steadiness of Mt. Conness were supreme, and the image of the heliotrope was like a minute star; but so soon as the Sun's rays struck the eastern flank of Mt.

Diablo the atmosphere around the observing station became so unsteady that observations were made with difficulty and little satisfaction.

We had a similar experience at the transit of Venus, Station Cerro Roblero, in New Mexico, in 1882. sunrise the atmosphere was so serene that we could see, with the five-inch equatorial, the small branches of the scant scrub growth on the dark, sharp, blue crest-line of the Organ Mountains, twenty miles distant. Immediately after sunrise the suddenly heated air, rising up the steep slope of the Cerro Roblero, just in front of the observatory, caused great waves of disturbed air to obliterate the branches of the brush and to exhibit the border of the Sun as a remarkably confused outline. The direction of these waves was very marked. At the time of the first contact of the images of Venus and the Sun the observations were made with difficulty and doubt, and micrometer measures were almost impracticable. The station was about 5,676 feet above the sea, and 1,655 feet above the Rio Grande and the Jornado del Muerte.

We have been thus prolix in order to indicate that the principal disturbance exhibited in the telescope, as well as to the unassisted eye, is in the immediate vicinity of the observing station. At trigonometrical stations, in disturbed conditions of the air, the confused and unsteady image of a heliotrope will exhibit a movement of 5" to 15" of arc. The observer could not see such movement if it took place rapidly at the distant station. If the heliotrope image at Mt. Conness were moved bodily sideways forty-four inches, the observer at Mt. Diablo would see it change only one second in amplitude, supposing the movement were slow and therefore capable of cognizance, instead of being very rapid and not then capable of detection. This exhibition of the locally disturbed atmosphere at the observing station can be readily produced artificially.

At Round Top station, in the Sierra Nevada, 10,435 feet elevation, we counted forty-seven forest fires that arose on the flanks of the forested mountains over which we were observing. The smoke gradually filled the Sacramento Valley to a height of 10,000 feet, and obscured the outline of the Coast Range Mountains; but we observed the heliotropes through this irregularly heated atmosphere with little difficulty, and at the close of the operations the probable error of a direction was only seven hundredths of a second of arc.

Besides the disturbance of the outer atmosphere near the observer, there is another source of disturbance in the air within the tubes of the great telescopes, especially in sunlight observations or at the sudden change of temperature at sunset. This is visibly exhibited in the blurred, unsteady and confused outline of the Sun and the Sun-spots projected upon the ground-glass plate of the horizontal heliograph tubeless telescope of forty-feet focus. In the transit of Venus of 1882 the image of the Sun at Cerro Roblero was projected through a forty-feet tin tube of large diameter, and was much blurred; but this was largely corrected when the tube was covered with a wooden roof not in contact.

Professor A. E. Douglass, of the Lowell Observatory, has shown that the waves of the disturbed atmosphere outside and inside of the large telescope tubes are distinctly visible to the naked eye when it is placed in the focus of the objective, as in the Foucault test. And even more than one series of such waves of disturbance at different distances and moving in different directions is not infrequent.

It is well known that to obtain the best results with the great telescopes it is imperative that the air inside the dome and inside the telescope tube shall have the temperature of the outside atmosphere.

At Arequipa, Peru, the Harvard Observatory was situated close to the valley of a mountain stream or arroyo, down which, on clear nights, a swift stream of cold air descends. Whenever this cold stream overflowed the banks and enveloped the observatory, and rose to the height of the objective, the seeing was immediately ruined for the rest of the night. In such circumstances, if the eye-piece of the telescope was removed and the eye placed in the focus, fine parallel, dark

lines could be seen moving swiftly lengthwise across the illuminated lens in the direction of the wind.¹

At San Francisco, in the strong "wind gap" of the Golden Gate, it sometimes happens at sunset, after a calm, moderate day, that star images are disc-like and steady; in a few minutes the westerly wind rises and brings in the fog-chilled air from the ocean, with flying patches of fog overhead, and the star images at once become diffused and nebulous, with an unsteadiness reaching an amplitude of 5" to 10" of arc.

Large volumes of air, each of different but uniform temperature, projected across a line of sight at a great distance from the observer, do not necessarily produce abnormal images of a star or heliotrope; they seem to act as prisms, and deflect the line of light so as to exhibit abnormal horizontal or vertical refraction without any marked unsteadiness. Along the face of a great mountain wall we have measured a slow change of azimuth of a signal amounting to 65" of arc, due to the gradual rising of the morning temperature of the air immediately adjacent to the eastern rocky face of Mt. Constitution.

There are so many conditions conspiring to a disturbed atmosphere that it necessarily acts in various ways difficult to predict. Where there are regular, irregular or confused atmospheric waves moving at different distances from the objective, and in different directions, they necessarily give different images of the star at different foci, and at each change they bodily shift the image near the focus, and also change its form. Professor Douglass' observations are very instructive in this matter.

When volumes of unusually heated air pass over the objective they may act as a species of air lens which suddenly and irregularly spreads out the image of the star at the focus; but no change of focus will bring the image to condensation. This we first experienced at Point Concepcion in 1850, where the perceptibly hot volumes of air from

¹ Douglass, "The American Meteorological Journal," March, 1895, p. 395.

the higher gulches were driven over the observatory by an incoming cold north wind from the Sierra Santa Inez.

It is sometimes reported that stars become very unsteady in a strong wind; yet we have determined micrometer values by observations upon a close circumpolar star during a fierce "norther." In geodetic observations between Mt. Diablo and Mt. Conness, on a line of 143 miles across the Sacramento Valley, we witnessed a strong norther blowing down the valley and carrying vast quantities of dust across the line of sight; but the wind did not reach the observing station on the first day, when the heliotrope image was fairly good, but was moved bodily by horizontal refraction two or more seconds of arc from the normal direction.

OBSERVED OCCULTATIONS OF RED STARS AT THE BRIGHT LIMB OF THE MOON.

Referring now more particularly to the details of some astronomical observations, we give a few instances from our experience and that of others.

On September 18, 1848, about seven and one-half hours in the morning, we observed the occultation of a Tauri by the bright limb of the Moon, using a telescope of probably two and one-half inches aperture and moderate power. The red star touched the bright limb, and we noted the time mentally, because it did not instantly disappear. continued the watch until the star was unmistakably within the apparent limb, when it disappeared instantly, about two and a half seconds after the first apparent contact. We at once submitted the case to our chief, R. H. Fauntleroy, who said the disappearance was the true time of the occultation, but he gave no explanation of the phenomenon. We then submitted the observation to the Superintendent of the United States Coast Survey, Professor A. D. Bache, who wrote to the Royal Astronomer (Airy) on the subject. The reply was that he personally had never observed the phenomenon, but there were similar cases on record. gave no explanation.

In the trigonometrical survey of Admiralty Inlet and Puget Sound, during the approach of a southeast storm which finally brought up dense clouds, a heavy squall and rain, we observed a Scorpii (April 22, 1856,) with a three-inch Fraunhofer telescope and astronomical eye-piece, power about 70. The disappearance of the star was behind the bright limb, and the record states that "the time denotes the instant of the disappearance of the star after it had been projected upon the body of the Moon for about two and one-half seconds, certainly not less. The ruddy color of the star showed distinctly upon the body of the Moon, and the instant of disappearance was as accurately noted as if it had disappeared behind the dark limb. Having once before observed the same phenomenon, we were fully prepared for it."

In November, 1886, we presented a paper to the California Academy of Sciences upon the occultation of a Tauri on the twelfth of November. Three instruments were used at the disappearance: two three-inch Fraunhofers, power 100, and a two-inch, power 55. The atmosphere was clear and moderately steady, the stars showed signs of unsteadiness, and the Moon's border appeared reasonably sharp. The telescopes were not large enough for such observations, but an intervening house prevented the use of the six and four-tenths inches Equatorial.

The star was visible to the unassisted eye to within four minutes of contact. When it was a few seconds from the Moon's bright limb the star became invisible in the two-inch telescope. In the three-inch Fraunhofers the star did not disappear when it touched the apparent limb of the Moon, but continued to move upon the disc until it was fully one and one-half times the diameter of its spurious disc on the Moon, when it disappeared with the instantaneity of such phenomena. The star grew somewhat difficult to see after it entered upon the factitious limb, but its reddish hue left no doubt in the minds of the two observers, who differed 0.07 second in the time of its disappearance. They estimated that it was three seconds of time on the limb. At

emersion from behind the narrow, dark edge of the Moon (which was one day past the full) the 6.4-inch Equatorial noted the reappearance 0.17 second earlier than the two three-inch telescopes.

At the Chabot Observatory, thirty-six seconds of time east of the Davidson Observatory, the observer used the Clark eight-inch Equatorial for the same occultation. The atmospheric conditions were nearly the same as mentioned. The star advanced upon the apparent limb of the Moon, but not so far as above mentioned, and some of the apparent rays of the star projected outside the Moon's border.

On March 29, 1887, we observed the immersion of a Tauri at the dark limb, and the emersion at the bright limb; the former by daylight, and the ash-gray limb not visible. The disappearance was instantaneous. At reappearance the Moon's limb was blurred and very unsteady, and the star reappeared upon this blurred bright image inside of the outermost limit, which was very fuzzy and decreasing in brightness outward. The star was not so bright as anticipated, but its almost sparkling red color left no doubt whatever in our mind as to the nearest tenth of a second of the epoch. The star left the limb in two and one-half or three seconds, when it appeared much brighter. At emersion a power of 250 was employed.

We do not mention the hundred and more occultations which we have observed when the above phenomenon was not present, or when the smallness and whiteness of the star may have prevented its detection.

OTHER OBSERVED OCCULTATIONS OF THE STARS BY THE MOON, AND OF STARS AND SATELLITES BY JUPITER.

In 1890, the Astronomer Royal called the attention of the Royal Astronomical Society to the occultations of ζ Tauri (3.0 magn.) that presented matter of "interest" to observers and astronomers. On September 16, 1889, Mr. Turner, of the Greenwich Observatory, observed the occultation of the same star by the bright limb of the Moon with

the Lassell Reflector of thirty-four inches, and Mr. Lewis with a refractor of three and three-fourths inches. Turner noted: "No projection; disappeared instantaneously at bright limb." Mr. Lewis noted that "the star touched the limb of the Moon five seconds before the observation, and was slightly inside the limb." It appeared "as a brilliant spot in the Moon, and disappeared suddenly at the time given above." In the same number of the "Observatory" where this report is made Mr. Ranyard says that "in the case of Jupiter there are instances * * * where one or two stars have apparently been seen through the limb of the planet. There are such a number of these observations that we cannot doubt the planets have not a sharp limb; they seem to be surrounded by an atmosphere of great, depth, or rather a gaseous envelope, in which clouds or dusty matter float in irregular masses." This is an extraordinary statement, and, in our judgment, based upon a misconception of the cause of these phenomena.

The outline of any cloud system at such enormous distances from the Earth as Mars, Jupiter and Saturn would subtend so minute an angle that the outline of the planet would necessarily appear sharp, even if the assumed cloud were irregularly distributed. The Sun's outline appears remarkably sharp when our atmosphere is steady, and yet we know that extraordinary disturbances of the solar surface, far beyond our experience, are constantly taking place.

On May 10, 1895, Mr. John Tebbutt observed the occultation of Antares at Windsor, New South Wales. The steadiness and definition of objects were reported very satisfactory. The instrument was an eight-inch objective, with a magn. power of 74, and "Antares, quite brilliant to the last moment, was closely watched till it came into contact with the bright limb; but then, instead of instantly disappearing, it seemed to cut its way into the disc during two or three seconds, and vanished instantaneously. The reappearance of Antares (62 1-3 minutes) later at the dark limb was remarkably instantaneous." It should be noted

however, that the observer was not looking at the spot where the star reappeared, and thereby lost the earlier reappearance of the well-known companion; and at any rate he could not have seen the star reappear with sudden brightness unless the dark limb was undisturbed. The same occultation was observed at Waverly, Sydney, by Walter F. Gale, under fairly good conditions and thick haze. With a six and a quarter-inch objective and magn. power 140 "the disappearance was instantaneous at a notch formed in the Moon's limb by two peaks." This description of the point of ingress indicates that the limb of the Moon was steady and sharp.

The same occultation was also observed at Warrickville, near Sydney, by C. J. Merfield, with a seven and a half-inch reflector, with power 170. "The definition was fair, although hazy at the time of disappearance, which was not instantaneous, as is usual."

Professor Young, in his "General Astronomy" (p. 246), refers to the projection of a star on the Moon's dark limb in the following paragraph: "In some cases observers have reported that a star, instead of disappearing instantaneously when struck by the Moon's limb (faintly visible by earthshine), has appeared to cling to the limb for a second or two before vanishing, and in a few instances they have even reported it as having reappeared and disappeared a second time, as if it had been for a moment visible through a rift in the Moon's crust. Some of these anomalous phenomena have been explained by the subsequent discovery that the star was double, or had a faint companion." No further explanation is attempted. We have purposely watched stars occulted at the ash-gray limb of the Moon, but have never been able to see a sufficiently bright and defined limb to note whether it was invaded by the star before its sudden disappearance.

In the publications of the Astronomical Society of the Pacific for November 30, 1889, Professor Barnard, of the Lick Observatory, says that "at a number of occultations of the satellites [of Jupiter] I watched carefully for any evidences of their being seen through the edges of the

planet, but saw nothing of the kind. Professor Holden informs me, however, that with the thirty-six-inch Equatorial the whole disc of a satellite has been visible within the planet's atmosphere at every occultation he has observed." In the "Astronomical Journal," volume VIII, page 64, there is a record by these observers of the occultation of 47 Libræ (6.4 magn.) by Jupiter, on June 9, 1888. With the thirty-six-inch objective and power 672, the images were below the average of good seeing. Director Holden reports that "the star entered the limb and was seen bisected" at 1m 30 after it had touched the outer edge. "The entire image of the star was seen, inside as well as outside the limb, being easily distinguishable from the planet's surface by its brilliancy and peculiar color." In 2^m 35" "the star was entirely inside the limb, but still visible. For the next ten seconds the star was alternately visible and invisible, and the planet's limb was quite unsteady." In 2m 51s from the star's first touching the limb it was certainly gone. Professor Barnard observed the same occultation with the twelve-inch objective, reduced to eight inches because "the images were too unsteady with the full aperture" (magn. power 240). He noted the time of "contact of the following edge of the star with the preceding limb" of Jupiter. At 1m 12 after, he star was partly on the limb; at 1^m 51^s the star was seen by glimpses to that epoch, and three seconds later it had certainly disappeared when it had advanced about three-quarters of its disc within the limb. On the usual scale of seeing, the conditions were below the average; but even when the star had encroached on the limb the disc was small, round and bright, and as clearly defined as that of a satellite entering transit. certain diminution of its light was observed.

Professor Barnard makes no allusion to the color of the star, and as its spectrum is recorded as that of the first type, there seems no reason why the first mentioned observer should attribute a "peculiar color" to it.

Under date of April, 1894, Professor Barnard thinks "astronomers should reject the idea that the satellites of Jupiter can be seen through his limb"; since, under good

conditions, with the Lick thirty-six-inch objective, "the limb of Jupiter has appeared perfectly opaque, as in all my previous observations with smaller telescopes." But he makes no reference to the character of the factitious limb of the planet in unfavorable conditions of the atmosphere.

At Melbourne, September 14, 1879, the occultation of 64 Aquarii (6.9 magn.) by Jupiter was watched in the great reflector. The star was thirty-five seconds in disappearing, and remained visible ten seconds longer as a speck of light seen through ground glass. This speck "also disappeared gradually." Proctor says the observers personally assured him the phenomenon was not due to irradiation.

In 1878, at the Adelaide Observatory, two observers (Messrs. Todd and Ringwood) saw the occultations of satellites I, II and III upon certain occasions "within the disc of the planet" at disappearance, and once at reappearance. "In every other case the occultation was perfect at the limb." This latter sentence was not quoted by Proctor.

Dr. E. C. Pickering, Director of Harvard Observatory, has described an occultation of D. M., 23° 1087 (7.3 magn.), by Jupiter, April 14, 1883. He used the fifteen-inch objective, with achromatic eye-piece, power 400. "For a period of about ten minutes after disappearance was observed, the star is recorded as 'suspected.' The record states that for some time previous to final disappearance the star alternately disappeared and reappeared without cause; seeing pretty good and uniform throughout.' At the reappearance, the limb of the planet was watched continuously for forty-nine seconds, at the beginning of which the star was not visible, and at the end of which it was distinctly seen, remaining visible thereafter."

In our experience in observing Jupiter, we have never seen the border sharply defined when using powers of 500, but atmospheric conditions have never been supremely good at the times of observation. In observing the occultation of Jupiter's satellites through an unsteady atmosphere, our fellow-observer, with a smaller telescope and objective

of two and one-half or three inches, lost the satellite much sooner than we observed its disappearance in the 6.4-inch Clark Equatorial, when we followed it into the factitious limb; and with a disturbed atmosphere this advantage should always pertain to the larger objective and higher power.

Numerous observers might be quoted who have seen stars and satellites projected within the apparent limb of Jupiter at occultation. Some of the details are rather startling, and perhaps the most notable is that by Admiral Smyth, in 1828, supported in part by two other observers at stations a few miles distant. The satellite II remained for some minutes projected upon the apparent edge of the planet, and thirteen minutes afterwards it was outside of the disc; then it remained visible four minutes and "suddenly vanished." If the observers had been experts, observing with instrumental means adequate to give sufficient light, definition, and size to the images — noting the times with accuracy, and fully recognizing the effect of the locally disturbed atmosphere — we are satisfied that some satisfactory explanation would have been reached.

Such details as these, and others upon different occasions, are rather astonishing. Such remarkable conditions must be due to imperfect instrumentation, to inexperience, to weariness or lack of quick and positive accommodation of the eye, to erroneous estimates of small intervals of time, to extraordinarily abnormal conditions of the atmosphere, to intervals of unconscious cerebration, or to gross mistakes. It was from the abnormal observations at Melbourne that Proctor undertook to deduce the depth of Jupiter's atmosphere, and concluded that the star 64 Aquarii was seen through a range of 10,000 miles of atmosphere below a depth of 300 miles.

We may here mention incidentally that for many years we have been on the outlook for Saturn and his ring system to occult some star of moderate magnitude; but the phenomenon has not occurred in our experience. We were anxious to learn how the ring system would treat the star.

SIMILAR PHENOMENA AT TOTAL SOLAR ECLIPSES.

Many reports of observations of total solar eclipses and transits of Venus and of Mercury over the Sun's disc are painfully discordant, misleading and uninstructive. They betray inexperience and lack of knowledge of the local physical disabilities that may present themselves. It would almost appear as if those who had the least experience were the most authoritative in their opinions. And certainly, when the results are published, there is little or no discrimination made in assigning proper weights to them. Some observers make no mention of their defective eyesight, and we have personally known observers; quoted as authority, that should never have been trusted to attempt any observation of precision.

The elaborate reports of the total solar eclipse of 1869, in the United States, by many observers in different localities, are quite instructive in the unconscious exhibition of contradictory statements and inappropriate adjectives. Two observers at the same station reported directly opposite conditions of the steadiness of the limbs of the Sun and Moon. One said they were defined with the utmost clearness; another sent us drawings to explain his statement that they were "boiling excessively." And yet the observer who reported steadiness was in doubt twelve seconds of the time of contact, and took the mean of his limits of doubt. And it is evident that the many observers had different conceptions of what constituted the phenomenon of "Baily's beads." Some looked for, and evidently expected, the exhibition as a necessary and normal physical condition. The tabulated descriptions of the phenomena at totality range wildly; we find recorded: "no trace of Baily's beads;" "the phenomenon of Baily's beads lasted but a few moments;" "Baily's beads beautifully distinct and spreading over an arc of 30°;" "Baily's beads were seen fifteen seconds or more; they were long and thin, moved with the moon, and were unquestionably the effect of the irregularities of the Moon's contour exaggerated by

irradiation." One observer has given detailed drawings of the form of the "beads," and exhibits them with mechanical precision and hardness; as a matter of fact he was not a draughtsman nor a skilled observer, and yet his name carried great weight.

Similar Phenomena at Transits of Venus and Mercury across the Sun's Disc.

In our observations of the transit of Venus, December 1882, at Cerro Roblero, New Mexico, 5,676 feet above the sea, and 1,655 feet above the Rio Grande del Norte and the great arid plain of the Jornado del Muerte, there were, towards the close, occasional tremors or shiverings of the borders of the discs of the Sun and planet from slight tremulousness of our atmosphere; but the eye was not confused, as would have been the case if the discs had continued ill-defined and unsteady by excessive vibration. In the first case the eye could and did select its opportunity for micrometric measurements. But at this very period the assistant astronomer in charge of the photographic exposures reported the results unfavorably affected by this slight unsteadiness. It was a case where the eye selected a moment of steadiness, but the mechanical movement of the photographic shutter permitted no selection. The unsteadiness of the atmosphere at the time between the third and fourth contacts permitted a beautiful and unique exhibition of the fine, white, faint, crescent of coronal light apparently surrounding part of the disc of Venus as an illuminated atmosphere. The crescent was long, extremely thin, white, and as fine, sharp and regular as if cut by the finest graver; and we watched it die away in excessive minuteness. We made drawings of the exhibition. observer of this beautiful phase of the transit at a different station saw a similar phenomenon "shortly after the first external contact, when the limb of the planet was 'boiling," and "it was difficult to be certain whether it lay within or without the planet's contour * * * but it certainly appeared to extend at any rate within the circumference; and indeed it presented the appearance of 'Baily's beads' at the time of a total solar eclipse. Its whole depth was one-fourth of the planetary radius'; and the published drawing showed the broader part of the coronal light partly inside the planet's circumference when the planet was half on the Sun's disc. Astr. Nach. 2,481. Here we have exhibitions of the same or a similar phenomenon at the same transit under widely different atmospheric conditions; and the first is surely to be taken as better representing the true or normal phase of the phenomenon, and the latter is to be reckoned as abnormal and misunderstood.

This phenomenon of the so-called "atmosphere of Venus," though not connected with the disturbance of our atmosphere, is thus seen to be affected by it just as much as the outline of Sun or planet. Mouchez has called it the "pâle auréole * * * to be attributed in part to the atmosphere of the Sun rendered visible by contrast, and also in part by the atmosphere of Venus." Heraud and Bonify designated it as the "filet lumineuse;" and Airy says this "penumbra must, of course, be considered a part of Venus;" and elsewhere he says "the partial illumination of the atmosphere of Venus introduces difficulties of observation" etc. One observer says that this ring of light around Venus enabled him to see the planet twenty-four minutes before contact. One of our astronomers who had witnessed the transits of Venus of 1874 and 1882 asserts that "there seems to be absolutely no way of escaping from a new difficulty—the planet's atmosphere causes it to be surrounded by a luminous ring—as it enters upon the Sun's disc, and thus renders the time of contact uncertain by at least five or six seconds." Another admits "the disturbance of the image by irregular refraction in the Earth's atmosphere," but declares that "we must look to the chief cause of the great discordances" of the times of contact of Venus and the Sun, "in the atmosphere which surrounds Venus." And he further says, that "the cruel manner in which all the phenomenon are modified by the atmosphere of Venus is not easy to explain." Another declares "the

planet was surrounded by a ring of light, as bright as the Sun, that pushed the edge away from it; and no actual contact could be observed." And yet there was no black drop, no ligament and no distortion reported by the observer.

It is admitted that there is no atmosphere enveloping the Moon, and yet Royal Astronomer Stone at the Cape of Good Hope observed the outline of the Moon projected against the Sun's corona five minutes and eight seconds before the total phase of a solar eclipse. We reported a very faint exhibition of this phenomenon January 11th, 1880. If the corona of the Sun is the visible arc of illumination in this case through contrast, we are entirely justified in assuming it to be the agent of illumination at the circumference of Venus; and on account of the irregularity and inequality of the brightest parts of the corona, it may be seen at one part of the planet's circumference and not at another, or it may be seen all around the planet. A critical examination of the reports clearly demonstrates that this faint illumination on the border of the dark body of the planet is seen as (1) part of a circumference; (2) at different parts of the circumference; (3) of varying breadth at different points of its length by the same observer; (4) as wholly encircling the planet. If it were the atmosphere of Venus it would be uniform and continuous, unless a Venus cloud system interfered irregularly. Young says (p. 159) that at a total solar eclipse there is "not any ring of light running out on the edge of the Moon like that which encircles the disc of Venus at the time of the transit."

With a slight digression, we mention one or two vagaries of observers of the transits of Mercury.

At one of the recent transits where the observers were side by side, one reported the "definition of Mercury sharp and steady," and the "limb of the Sun undulating," as if the two objects were unequally affected. The other observer described the "limbs of the Sun and Mercury loosely connected by a patch of haziness oscillating between them;" and at another phase the "undulations of the Sun's limb

occasionally reached Mercury;" leaving the inference that the planet was steady. At yet another station the "planet appeared with rippling fiery and black balls chasing each other between the planet and the Sun." In the transit of 1878 one observer "was surprised at the absence of glare and tremor; and the edge of the Sun's disc was clearly defined and remarkably steady with the exception of a few notches and scratches."

We had been fortunate in our observations of the two transits of Venus, and of several transits of Mercury, never to have seen an exhibition of "black drop" or "ligament," except at the transit of Mercury in 1891, when the atmospheric conditions of San Francisco were very unfavorable although the sky was clear; the limbs of the Sun and planet were both spurious or factitious on account of excessive vibration; and the observation was necessarily difficult and doubtful. Under such adverse conditions the observation may be very wild, or it may turn out very good; but certainly the observer cannot assign much weight to the epoch noted.

INSTRUCTIONS FOR OBSERVING THE TRANSIT OF VENUS.

In re-examining the large number of reports of the transits of Venus of 1874 and 1882, we have gathered forty or fifty expressions of the observers in their endeavors to describe the phenomenon usually known as "black drop," "ligament," or "filament."

This need hardly be wondered at. The British Instructions of 1882 assert that the phenomena seen by most observers near the time of contact are of a complex character, and extend over considerable intervals of time. These instructions surely conveyed the impression that these complex phenomena were the normal physical conditions. They added confusion to previous descriptions by mention of the "light of the cusps;" and evidently regarded the exhibition of haze, or ligament, as "the glimmering of the light of the 'auréole,' 'penumbra', or 'sunlight' refracted through the

atmosphere of Venus across the dark space between the cusps." And further, if a "pure geometrical contact" (which is the only line that can be given for contact) is frustrated by haze, shadow, ligament, or black drop, then the last marked discontinuity of the illumination of the Sun near the point of contact is the epoch to be recorded if it "is distinctly recognized as independent of mere atmospheric tremor."

The American Instructions were mainly based upon the appearances of 1769; and declared the "atmosphere of Venus clearly illuminated." They refer to the difficulty of observing the moment of tangency on account of imperfection of vision, irradiation produced by the Earth's atmosphere, and imperfections in the telescope; and then mention the difficulties to be expected by atmospheric undulation.

One of our eminent astronomers accepts the explanation of Lalande, that the phenomenon of "black drop," etc., is caused by irradiation at the bright object; and that this irradiation arises from a number of causes, imperfections of the eye, imperfections of the telescope, and the softening effect of the atmosphere upon a celestial object when seen near the horizon. He likens it to a narrow and less bright false edge around the bright object; and says that this band will appear narrower the better the telescope and the steadier the atmosphere. He furthermore says that in the observations of the transit of Venus of 1874, with the improved instruments, very few of the experienced observers noticed any distortion at all. Later on he adds that "in the varied forms presented 'when the air is not still,' we recognize all the peculiar appearances described by the observers of 1769." In 1874 the Mexican observers at Yokohama reported to us a decided exhibition of "black drop."

Colonel Tennant has remarked of the black drop phenomenon, "there is no doubt in my mind that the outer part of the Sun is never free from the result of outstanding astigmatism." We have astigmatism of the human eye, and astigmatism of the telescopic objective and ocular, but we do not understand to which he applies the term, if to either of

them. And one of our best astronomers, in reviewing the physical and other conditions of the 1761, 1769 and 1874 transits, summed up his deductions by saying that "the black drop, and the atmospheres of Venus and the Earth, had again produced a series of complicated phenomena extending over many seconds of time."

CURIOUS DESCRIPTIONS OF THE PHENOMENA.

With much more speculation of similar import we should be prepared for the crude descriptions and attempted explanations given by the observers. They range from a 'Chinaman's hat' to a 'pear-shaped planet,' and are even stretched out to a 'gourd shape.' The descriptions and explanations by the same observer are sometimes curiously contradictory or vague, as: 'the limbs were boiling violently,' 'yet quite sharp and doubt only three or four seconds;' there was 'black drop' but 'no distortion;' 'no distortion' yet the 'limbs of the Sun and Moon were spinning;' 'interference lines;' 'Venus serrated;' 'the Sun's limb had lost its sharpness from the overlapping of Venus' atmosphere;' the 'shadow of contact;' from the overlapping of the two 'penumbras of imperfect definition;' and most remarkable and incomprehensible, 'the sympathetic attraction or assimilation' of the limbs of the Sun and the planet at the second contact but no 'mutual attraction' at the third.

In Egypt, in 1882, one observer paid particular attention to detect the black drop and could not see it; another observer at the same locality observed the black drop. The imagination would seem to have played a part in the observations. One observer saw Venus twenty-four minutes before contact; and near the first contact he saw "a distinct cone of shadow thrown away into space;" and his drawing is stronger and stranger than his description. In 1874 the chief astronomer of one of the foreign expeditions declared to us that the phenomenon was simply and solely a case of diffraction.

Errors of Observation.

It is therefore astonishing to note that under such adverse conditions for accurate observation the times of contacts are noted to tenths of seconds. As two seconds of time mark the apparent relative movement of the bodies about one-tenth of a second of arc, we need not wonder that some of the observers were not sure of the minute; and in one case an error of three minutes could not be fixed. occasional and accidental distortion of the planet's disc in such transits had called for the determination of the epoch of the geometrical contact of the limbs of the images of the two bodies and for other appearances; but under such unfavorable conditions the judgment of the best observer may reasonably have been at fault, and his recorded epoch of contact very wild. This is shown by many illustrations of the distortion where the outlines of the "black drop" are drawn with a hardness and positiveness that are certainly uninstructive, and unsuggestive of the cause.

The difficulty of observation is made painfully manifest in the experiments at Washington early in 1874, when most of the observers practised upon an artificial transit of Venus to determine the times of the four contacts. observations range from four seconds before the first contact to twenty-eight seconds after; and even at the second and third contacts, from twenty-one seconds before to seventeen seconds after the epochs. These extraordinary personal equations must surely have been due in part to inexperience, and mainly to the disturbed conditions of the atmosphere. And yet the mean value of a series of such observations was applied to the actual observations in the field upon the Sun and planet, to reduce them to a systematic series. Had these preliminary observations been made in a serene atmosphere, the apparent personal equations would have been brought to normal and reasonable limits, notwithstanding one observer declares that "the optical edge of a bright body is not, and in the nature of things, cannot be, absolutely sharp in the eye or in the telescope." The great discrepancies arose in large

measure from the unsteadiness of the short line of intervening atmosphere near the ground; and we then related our experience at great elevations and over heated plains, and urged the occupation of elevated and isolated stations as the most effective means of avoiding an unsteady atmosphere in such costly and important observations.

OBSERVATIONS OF SOLAR ECLIPSES UNDER DIFFERENT ATMOSPHERIC CONDITIONS.

Professor Dr. Schaeberle of the Lick Observatory observed the total solar eclipse of October 9, 1893, at 6,600 feet elevation, on the western flank of the Andes in Chili. He was eminently successful in all his observations on account of the extreme steadiness of the atmosphere. The Sun's image, projected by the six-inch equatorial upon a white cardboard, looked "more like an engraving than an optical image." Aubertin, at the same station, said that during the eclipse "the atmosphere was absolutely pellucid"; he had had experience at Gibraltar in 1870.

Our experience in observing the above eclipse at San Francisco as a partial phase was the reverse of Professor Schaeberle's, but very instructive. We condense the report. The images of the Sun, and the micrometer thread were projected by the 6.4-inch equatorial upon a white sheet of The apparent diameter of the Sun's image was about twenty-two inches. The atmosphere was unsteady, and the border of the Sun was confused and blurred, and lacked the solid or consistent brightness of the disc. factitious border was about half a millimeter broad at the The solar spots were confused and their details were not distinguishable. As the time of first contact approached we watched the predicted point of contact, not for the first indentation of the Sun's disc, but for the first commingling or overlapping, so to speak, of the factitious image of the Moon's border with the factitious image of the Sun's border. There first appeared a very faint darkening of the confused and apparently expanded border of the Sun's limb. noticed it when it was about three millimeters long; the

disturbance of the limb was very great. The dark commingling or overlapping increased in length, breadth, and darkness; and at last changed to a line of blackness when the actual limb of the Moon's image touched upon the Sun's condensed, brighter and actual border. There was no hesitation in noting the time of this contact by several observers. At the time of the last contact, four of the observers watched the phenomenon. The borders of the two discs were more unsteady than at the first contact, and the reversed order of the first contact-appearances took place. A great mountain range of the Moon was the last to disappear. The two exhibitions were very instructive.

At the total solar eclipse of January 11, 1880, on the Sierra Santa Lucia, 6,100 feet above the sea, we observed the phenomenon under peculiar circumstances fully detailed in the official report. The atmosphere was beautifully serene after a prolonged and terrific storm of wind and snow. The limb of the Sun was not absolutely steady but exhibited occasional tremors or shiverings, and there was no disturbance of the limb at first contact. "The cusps were very sharp and clear, and whenever a tremor occurred on account of any slight atmospheric disturbance these cusps were apparently doubled." (At Oakland where the atmosphere was much disturbed the cusps appeared confused and blunted.) As totality approached, the crescent of the Sun was remarkably long and narrow on account of the slight difference of the apparent semi-diameters of the Sun (16' 18".1) and the Moon (16' 23".5). The last line of the crescent was 30° to 40° long before it broke. It exhibited no distortion from atmospheric disturbances except an occasional tremor or shivering. The cusps, before the crescent was reduced to a line, were remarkably sharp, curved points, as if cut by the finest graver. The breaking of this last thin line of sunlight was occasioned by the intrusion of the lunar mountains and the inequalities of outline. It presented the appearance of a line of bright dots and dashes, and black spaces. There was no wavy motion to interfere with this exhibition; whenever a bright spot or a line

disappeared it was instantaneous, and gone forever. The moving dots of the "Baily's beads" were absolutely wanting. At the last contact of the eclipse the atmospheric conditions were wholly changed. The atmosphere was in a remarkable state of undulation and the limbs of the Moon and Sun were moving in great rapid waves, and the observation was unsatisfactory. The Sun set below the ocean horizon about ten minutes later and we should have expected a quiet atmosphere, but the warm Sun rays heating the air upon the steep, snow-covered ocean-side of the mountain mass caused rapid evaporation of the snow, and irregularly heated currents of air to flow over the station. At this eclipse we called attention to the less darkness of the sky adjacent to the advancing body of the Moon, due to contrast with coronal effects.

At the solar eclipse of October 30, 1883, we projected the images of the Sun and Moon upon a sheet of white paper, and studied the disturbed outline of both objects. The greatest obscuration occurred just before sunset, when the Moon was half way over the Sun's disc. Owing to the extreme refraction at this zenith distance, and the "exceedingly great boiling" of the borders of the two images, the "distortion of the cusps was striking and peculiar."

In contrast with these two exhibitions of great atmospheric unsteadiness, we introduce an experience approaching that of Professor Schaeberle's above mentioned.

We observed the total solar eclipse of August 7, 1879, on the Chilkaht River in Alaska, near the end of heavy, cloudy weather, when the atmosphere had become clear and steady. At the first contact "the limb of the Moon was very sharply defined, and the outline of the Sun was very steady and sharp." Just before totality "the crescent was very beautiful to the unassisted eye, and in the telescope." In the three-inch Fraunhofer, with moderate power, the "borders of the Sun and Moon were remarkably steady and very sharply defined. In twenty-four years of practice in observing we have rarely, if ever, seen them under such favorable circumstances. We observed them without any shade,

and followed the Sun's border to the instant of disappearance. The bright, long, narrow crescent was sharply and regularly defined throughout; the extremities were clearcut and pointed. As the width and length of the crescent decreased, this sharpness of outline and regularity of form were maintained until it became a fine line of *living* white; and, shortening rapidly, it disappeared as a very short, fine, distinct line, and not as a star at its disappearance. There was no breaking of this line into points or heads; no wave motion along it; no disturbance whatever of continuity or regularity of form."

"A feature of the phenomenon of totality was the vivid impression that the dark body of the Moon stood out clearly and unmistakably in relief in the space between the observer and the coronal brightness around the obscured body of the Sun, and did not lie flat and upon it, as in a picture." This perspective effect resulted from the serenity of the atmosphere, the sharpness of the Moon's outline, and an impression that the dark Moon was very close to us.

GRAPHIC EXHIBITIONS OF UNSTEADINESS.

If it were necessary to add graphic demonstration to the effect of the disturbed atmosphere already described, we have it in the photographs referred to in the following note by Warren de la Rue, where he describes the method of photographing the Sun's disc, in a very small fraction of a second. He says, "So rapid is the delineation of the Sun's image that fragments of the limb, optically detached by the 'boil' of our atmosphere, are frequently depicted on the collodion, completely separated from the remainder of the Sun's disc; more frequently still from the same cause the contour of the Sun presents an undulating line." To this case can be added a photograph of the Sun taken at the Lick Observatory January 14, 1897; wherein the factitious limb is like a flocculent border of cotton or wool with ragged holes through the relatively faint, irregular outline

¹ Proc. Brit. Assn. Adv't. Sci., Aberdeen, 1859, page 151.

of the disc; and several cloud-like areas actually detached. The breadth of the thin border is about 6", and the whole factitious breadth must be more.

It seems a physical impossibility that we should be able to detect any irregularities of even a dense atmosphere at the border of the Sun. If that body were to decrease 45 miles in diameter, our instrumentation would not be able to measure it under present conditions. Much less could we detect it if there were actually rolling billows of the exterior matter of the Sun 45 miles high around its border. They would subtend but 0.1" in height; a quantity covered by the finest spider thread in the telescope. Much less could we detect any changes of atmospheric conditions at the distances of Jupiter, Mars, Venus, or Mercury. Some great deep Sun spot just on the edge of the Sun would doubtless show a depression, but not any imaginable storm disturbance of the densest atmosphere, as we understand storms and waves.

OFFICIAL RECOGNITION OF THE FACTITIOUS BORDERS OF THE MOON AND SUN.

In still further confirmation of the existence of the spurious limbs of the Moon and Sun under unfavorable atmospheric conditions, it is only necessary to appeal to the representative of astronomical authority in the American Ephemeris or Nautical Almanac. In that government publication an empirical correction of 2".5 is applied to the Moon's semi-diameter in order to represent the observed value in meridian instruments. But this "constant is omitted in the computation of solar eclipses and occultations as due to telescopic and ocular irradiation" (p. 528, 1899). This 2".5 of increased semi-diameter may represent the average measure of the factitious border, but certainly it is frequently much greater.

In many years of experience upon the Pacific Coast of the United States in observing lunar transits, we have learned to expect wild results when a markedly factitious bright limb of the Moon was observed, the resulting longitude being always affected as if the diameter of the Moon were too great. At times, when the vibration or undulation of the disc of the Moon was not rapid, the sharp, solid limb could be observed even with a faint, spurious, vibrating outline beyond it. In 1889-'90, during lunar transit observations for longitude at San Francisco, our party had a case of spurious disc from excessive diffusiveness, with a predicted error in the resulting longitude that was verified upon reduction. This clearly indicated that even the official empirical correction may frequently be too small; while in times of supreme steadiness of the atmosphere and resulting sharpness of the limb of the Moon, this correction is not required.

If this factitious diameter belongs to the Moon, the Sun is much more likely to carry a more pronounced factitious diameter, and every observer must have frequently watched its wildly boiling limb flaring and leaping across the threads or rolling forward like waves of flame along the horizontal thread. This factitious border is in effect tacitly acknowledged in the American Ephemeris above referred to, where "the adopted semi-diameter of the Sun at the Earth's mean distance is 16'02". In the computations pertaining to eclipses, Bessel's semi-diameter 15'59".788 has been adopted." It appears to us that the explanation in the American Ephemeris of the cause of the acknowledged spurious diameter of the Moon is erroneous.

GREAT ELEVATIONS FOR OBSERVATION.

Although our experience has led us to advocate the selection of great elevations for astronomical observations of precision and research, yet elevation alone is not a panacea. The locality must present other favorable orographical conditions. Unfavorable conditions are great gulches, cañons, or narrow valleys lying directly under a summit and leading to it. These gulches become filled with highly heated air during two or three days of clear, calm weather, and the first wind from below drives this heated air over the summit and spreads stars out into unsteady nebulous films; the the rings of Saturn become woolly girdles, the crape ring is

invisible and the details of the belts of Jupiter are indistinguishable. And in such a location during daytime, observations of precision on the Sun are absolutely useless. The seeing upon a mountain peak may be generally good when there is no snow on the surface; and even remarkably good with snow, when the temperature is low and the wind is strong; but when the Sun shines and the temperature rises, and rapid evaporation takes place with light airs, the seeing becomes very bad. (Experience at 10,450 to 7,250 feet elevation.)

On Mt. Conness, in the Sierra Nevada (12,566 feet elevation), the geodetic heliotrope images were perfect until the afternoon Sun shone upon the 2,300 feet nearly vertical western face of that curious buttress; and then the uprising, irregularly warmed atmosphere caused the images to become unsteady. During the quieter moods of the atmosphere, we observed Polaris for azimuth in the middle of the day very satisfactorily with a telescope that would not show it in daytime at lower elevations or under less favorable conditions.

In 1872 we experimented in the Sierra Nevada at elevations from 7,200 to 9,500 feet with remarkable success; while another party of the United States Coast and Geodetic Survey sent for the same purpose to Sherman, 8,300 feet elevation, in the Rocky Mountains, had at times a very unsteady atmosphere. The Lick Observatory at Mount Hamilton, in the Diablo Range, at 4,209 feet elevation, is surrounded by unfavorable orographical conditions, especially for observations of precision in daytime.

It would appear that Newton attributed the apparent unsteadiness of celestial objects to the disturbance of our own atmosphere. "Telescopes," he writes, "cannot be formed so as to take away that confusion of rays which arises from the tremor of the atmosphere. The only remedy is a most serene and quiet air. Such as may perhaps be found on the tops of the highest mountains above the grosser clouds."

Precision Observations at Low Elevations.

And yet there are climatic conditions at comparatively low elevations, which are supremely favorable for observations of precision at night. The experience of the observers of the United States Coast and Geodetic Survey on the immense, elevated, arid plains from El Paso to San Diego is very instructive. During the hot cloudless days the atmosphere over the immediate surface of the parched earth was in violent unsteadiness, and the heliotrope images at even short distances flared out wildly like burning houses. They were the worst possible objects for observations of precision. After sunset the conditions were suddenly changed. With a cloudless sky and a minimum of aqueous vapor in the attenuated air (Barometer about 26 inches) radiation was quickly effective. The temperature fell many degrees in a short time, and the air became supremely quiet. The latitude telescope showed stars as minute discs with diffraction rings running along the micrometer thread with such extreme steadiness that it was impossible to be in doubt more than one-tenth of a second of arc in measurement; and in the transit instrument the star marched with absolute regularity across the reticule. It was an experience that an observer of over thirty years in the field declared he had never before enjoyed.

Per contra, on the low Yolo plains of the Sacramento Valley in California, we have had the azimuth signal-light (distance eleven miles), in a calm night, running wildly up and down the vertical thread of the theodolite through five minutes of arc, in an ever changing line of broken stars of the prismatic colors, and yet showing little or no horizontal motion. The range of height of this column of images was eighty-seven feet.

In the great Gangetic plains of India the night signals of the triangulation parties, when shown from towers of fifty feet elevation, frequently appeared as continuous columns of light sixty feet high.

In the triangulation of the western coast of Lower California by the United States Steamer "Thetis," the

observer informs us that the unsteadiness of the atmosphere and the irregularity of the refraction apparently lengthened the signal poles to a hundred feet and more; and the tripod supports were like great writhing snakes. Even upon some small low island in the ocean, where the climatic conditions are favorable, the atmosphere at night becomes very quiet and serene. From a vessel's deck we have watched the larger stars nearly reach the horizon with very little twinkling.

RECAPITULATION OF PHENOMENA AT OBSERVATION.

These examples are a few of the many experiences in our geodetic and astronomical observations, and in the descriptive experiences of a few other observers. And yet from recent publications there appear to be many observers who do not understand the cause of the phenomena, and who seem to think there must be something occult and unexplainable. We have therefore felt constrained to repeat this explanation which we have held and announced for many years. It seems to cover every phase of the phenomena.

In the occultation of stars by the Moon, a spurious and factitious limb of the Moon can be formed only and solely by the unsteadiness of our atmosphere more immediately surrounding the station of the observer.

In a serene atmosphere, the outline of the Moon is so sharp and clear-cut that the mountains and valleys thereon are very distinctively exhibited, and will bear the largest magnifying power. When the atmosphere begins to change to unsteadiness, the sharp outline of the Moon (or other object) is first affected by tremors or shiverings, which are so infrequent that the observer is able to select the actual border and its features. As the unsteadiness of the atmosphere increases, the tremors increase in frequency and in amplitude, until the border of the Moon becomes a confused, blurred outline, in which no serrations can be detected. The early shiverings usually denote the direction of movement of the disturbed air. Under the atmospheric

conditions of clearness and serenity, the apparently approaching image of the star is a beautiful, steady, minute disc with one or more delicate diffraction rings. Moon's white and sharply defined border exhibits all its serrations and irregularities. As it approaches the star, the diffraction rings disappear in the increasing light in the field of view, but the disc remains; and at their visible contact the disappearance of even the largest and brightest star is absolutely instantaneous; and no observer can be in doubt of the epoch beyond the tenth of a second. Under such favorable atmospheric conditions, the image of the star never enters upon the visible limb of the Moon, no matter what the size of the objective or the magnifying power employed. And with such conditions, the reappearance of a star from the bright limb of the Moon will be instan-If the star were apparently to make a near approach to the Moon along the dark north or south limb, where there are serrations, it might pass so close as to disappear behind the first mountain and reappear in the next valley (each phenomenon being absolutely instantaneous) to be swallowed up by the next mountain, or in its absence, to continue its visible course. We have heard (1846) the elder Bond describe such a phenomenon in his experience and it has happened once to ourselves. But when the atmosphere begins to change to unsteadiness, the star loses its diffraction rings, the nucleus is broken up and gradually diffused into a nebulous image, fuzzy and unsteady, with a brighter, irregular, dancing nucleus, or is spread out as a nebulous film as much as forty or fifty seconds of arc in diameter. This unsteadiness of the atmosphere throws the disc of the Moon into irregular vibrations or displacements of equal amplitude and duration, giving it a factitious border. With this disturbed and spurious limb the Moon approaches the diffused image of the star, both being in a state of great unsteadiness; but if the nucleus of the star be sufficiently large, bright, and colored, like Antares and Aldebaran, the impression of its image upon the retina of the eye is naturally more intense as an isolated spot than

the image of the whitish, confused, spurious border of the Moon, even when the former is within the latter. The action of the eye is unconsciously selective, but a certain effort of selection is made under the less favorable condition when the star is small or white. There is no effort at selection needed to receive an impression of the Moon's limb, although the actual limb may doubtless be detected, under high powers, inside this factitious border. pression of the image of the star is, therefore, continuous within the range of amplitude of the excursions of the disc of the Moon, but is instantly lost when the limit of this range of vibration is actually reached by the apparent nucleus of the equally unsteady star, and the true limb of the Moon occults it. With a large colored star all the phases of this phenomenon are unmistakable; with a large white star they may be somewhat in doubt, as in the case of 47 Libræ and other stars elsewhere quoted; with a small white star they will probably not be noted, especially in small telescopes with low power.

The exhibition of the phenomenon at the reappearance of a star on the blurred and factitious bright limb of the Moon should be in exactly the reverse order of the foregoing phenomenon of disappearance; and we have been fortunate in looking over our old record to find the original notes of the disappearance of Aldebaran behind the dark limb of the Moon, and its reappearance from the bright limb, on March 29, 1887, as elsewhere mentioned.

In this résumé we have confined ourselves to the exhibition of the normal and abnormal conditions in our atmosphere attending the phenomenon of occultations of stars by the bright limb of the Moon, or by Jupiter or any other planet, because the explanation virtually covers all associated phenomena in solar eclipses, lunar transits, transits of Venus and Mercury, and the vagaries of star images.

When our atmosphere is absolutely serene there is not and cannot be the slightest abnormal exhibition of form, size, march, or steadiness of images; or of doubt of instantaneity in the epochs observed. Under such a condition there would be no empirical corrections in the Nautical Almanac to the semidiameters of the Sun and Moon; and the diameters of the planets measured by different observers, and the right ascensions and delineations of the stars would be consistent within the instrumental and personal equations.

OTHER IMPORTANT RESULTS AFFECTED.

There is another and very important class of astronomical results affected by these factitious borders of the Sun and planets and the unsteadiness of the stars.

Dr. Newcomb says that the observed right ascensions of the mean of the Sun's two limbs, relative to the fixed stars, are affected by personal errors for which no means of elimination have been tried. He suggests personal error and possibly the effect of the Sun on the telescope. causes should be added the larger effects of the disturbed and factitious limbs; and in cases of steadiness, to diffraction of the limb at the spider line. He elsewhere notes "very large errors, both accidental and systematic, to which observations of the Sun are liable;" and again he regards "the constant error in declination of the Sun as something peculiar to the observer and the instrument." In another place he says: "There is a remarkable systematic difference in the observed A. R. of Mercury, according as the planet is east or west of the Sun, and therefore according to the illuminated side. The sign of the result shows that the reduction to the center of the planet was apparently too small, and then it is of interest to learn according to what law this error changed as the planet moved around its relative orbit."

Furthermore, the hurtful effect of observing upon the outer limb of the factitious limb of the disturbed Moon can be shown in the determination of the parallactic inequality of the Moon from meridian observations. Dr. Newcomb says the method is peculiarly liable to systematic error, owing to the fact that observations have to be made on one limb of the Moon when the inequality is positive, and on the other limb when it is negative. Hence if we determine

the inequality (125".5) by the comparison of its extreme observed effects on the Moon's right ascension, any error in the adopted semidiameter will affect the result by its full amount. This suggests that this gravitational method of determining the Solar Parallax would be more accurately employed by observing occultations of stars large enough to be seen through the spurious bright limb of the Moon. Moreover, the observations themselves would afford some data for the elimination of the error depending upon a factitious limb.

NEARLY ALL MEASURED DIAMETERS TOO LARGE.

In all instrumental observations for the right ascension of the Sun or Moon, and for their declination and diameter, it must be evident that the observer obtains accurate measures only when the disc of either body is sharply defined, devoid of tremor or unsteadiness, and unaffected by irregular and extraordinary refraction, without reckoning diffraction at the spider line, unknown instrumental errors, and peculiarities of observation. As these supreme conditions of steadiness are seldom obtained, it necessarily follows that the mean of any number of observations taken under different atmospheric conditions (say for example the diameter of the Sun, Moon, or planets) must be too large. The diameter can only be too small through error of observation, instrumental errors, diffraction of the spider line, or abnormal refraction.

With a disturbed atmosphere in observations for the determination of the right ascension of the Moon during the first half of a lunation, the observed A. R. of the limb will be too small and for the second half too large. Similar results will follow from observations of the I and II limbs of the Sun and planets. Therefore all published diameters of the Sun, Moon and planets derived directly from actual observations must be too large. Moreover, this presents a case where the mean of measured quantities is not the most probable value. The mean of all the minimum measures would be nearer the truth.

The amplitude of the excursions of the images of the Sun, Moon, and planets in a disturbed atmosphere is a variable quantity that can not be determined but should be avoided if practicable. To obtain the most trustworthy results in reasonable time, we need the fixed observatories located at points which conspire to give the best atmospheric conditions determined upon after systematic and exhaustive trial for special lines of research; the highest class of instrumentation; observers with ideal eyes (of which unfortunately there are very few); discrimination in the selection of proper times of observation; and a wise rejection of observations made under abnormal conditions.

NOTE. Since this paper was presented to the California Academy of Sciences, Professor A. E. Douglass of the Lowell Observatory at Flagstaff, Arizona, has published the second of his interesting papers upon "The Atmosphere, Telescope and Observer," and "Scales of Seeing." Pop. Astr. 1898.

PREFACE.

In March 1899, Dr. Keeler, late Director of the Lick Observatory, suggested that I should undertake, for a thesis, to reduce Professor Schaeberle's Meridian Circle observations for refraction, to discuss them completely, and to end with the construction of tables for the Lick Observatory. According to Astronomer Tucker, who is in charge of the Meridian Circle work at the Lick Observatory, the Pulkowa tables are not fully satisfactory for the reduction of observations made there, and those of Bessel are still less so.

After consultation with the late Professor Keeler, and with his consent, it was decided to forego the reduction of Professor Schaeberle's observations for the present, and to determine the Constant of Refraction from observations to be made by myself and to be reduced according to the method set forth in the following pages.

I wish to express my thanks to our late Director, Professor Keeler, for kind suggestions, for permission to use the Meridian Circle, and for absolute freedom in the method of procedure and in the reduction of the observations.

RUSSELL TRACY CRAWFORD.

Introduction.

1. The Meridian Circle.—The instrument with which these observations for refraction were made has been fully described by Astronomer Tucker in Volume IV of the "Publications of the Lick Observatory, 1900." For the sake of completeness, however, it will be described again in this paper.

The instrument was made by Messrs. Repsold and Sons, and was described by Professors Auwers and Krueger to be "in its construction in every way suited to be the chief instrument in an observatory of the first class." (cf. Vol. I, "Publications of the Lick Observatory.")

The aperture of the object glass, which was made by Clark and Sons, is 6.4 inches. Its focal length is 6 feet

4 inches. The tube of the telescope is in two parts, each of which is attached to a central cube. Their diameters decrease from 8.1 inches at the cube to 6.5 inches near their outer ends. An eyepiece giving a power of 90 and a field of 12' was used for these observations. The star images formed are not exactly round, but are slightly elongated in a direction parallel to the horizontal (declination) thread. There being no component of this elongation parallel to the vertical threads, it can have no effect upon observations for zenith distance.

The axis is 3 feet 2½ inches long, the distance between the counterpoises being 2 feet 2 inches. The pivots are 3.6 inches in diameter and are protected by brass covers. The telescope is furnished with clamps which, however, were never used during these observations. After the telescope was once set for a star it was not moved again to make the bisection, this being done by means of the declination micrometer. The value of one revolution of the screw of this micrometer is 48″.10. This value has been adopted as the result of many determinations made in past years. The micrometer thread is single.

The instrument has two circles, one of which can be rotated about the axis of the instrument while the other is rigidly fixed to it. They are both graduated to 2'. The degrees, as numbered, increase counter-clockwise. The diameter of the silver circle, upon which the graduations are marked, is 26 inches. There are 130 graduations to the inch. The fixed circle was used throughout these observations.

The four reading microscopes on each side are alike in all respects. They are 26.5 inches long and have clear apertures of 0.55 of an inch. Their powers are 40 and their fields are nearly one degree. The objectives are 5 inches from the circle and their eye ends project 8 inches from the frame holding them. The micrometer heads are divided into 60 parts. One revolution of a micrometer head carries the threads over one minute of arc of the circle. There

are two pairs of threads in every micrometer, but one of which is generally used.

There is a separate broken telescope for setting. This is supported on wyes attached to either pier and is at the level of the lower rim of the circle. By means of this the circle can be seen either from the north or from the south, so that the settings can be made very conveniently.

The illumination for both the field of view and for the circles under the microscopes is furnished by a Rochester lamp placed in a cylindrical case 9 feet from the axis of the instrument. This light also illuminates the heads of the microscope micrometers. Most of the heat from this lamp is carried out of the room by a pipe which extends from directly over the lamp through the roof to the outside air.

A simple mechanism enables the observer to change the system of illumination from a bright field with dark wires to a dark field with bright wires and vice versa; he can also reduce the amount of illumination at will.

The brick piers supporting the instrument are 34 inches by 44 inches at the floor of the room and 22 inches square at the top. The sides next to the telescope are vertical. They are cased in wood with a layer of felt between the surfaces. The platforms for the microscope reader are entirely disconnected from the casing of the piers.

The microscope bearers are 23 inches in diameter and 17 inches long. The wyes for the pivots of the instrument are attached to the inner faces of these frames.

The weights of the counterpoises hang from levers 26 inches long. The fulcra are in the centers of the levers and are 6 inches from the inner faces of the microscope bearers.

Two collimators, of same aperture and focal length as the Meridian Circle, are suitably mounted. The collimator micrometers are 35 feet 6 inches apart.

2. The Room.—The Meridian Circle house on Mount Hamilton has been most admirably designed. Its efficiency will become apparent from the meteorological data to be given later.

The observing room is 43 feet long (north and south) and 38 feet wide. All of the walls are double. The outer of the two is a louvre-work of galvanized iron which prevents the sunlight from touching any part of the building proper. The inner wall is of California redwood, and is separated from the outer by a two foot air space. The ceiling is also of redwood. It is about 16 feet above the floor. Above the ceiling is an air space 8 feet high at the observing slit and sloping to meet the east and the west walls.

The observing slit is slightly over three feet in width. The covering for the slit is in four parts which open outward. The ends are closed by shutters, each of which is in two parts opening inwards. Each end is also provided with a single shutter which slides up and down. For stars at zenith distances greater than 72 degrees these shutters have to be lifted. When down they are very efficient wind breaks.

There is a large canopy which can be rolled over the instrument to serve as an additional protection in stormy weather or when the instrument is not in use.

For a more detailed account of the instrument and room see Astronomer Tucker's account of them in Volume IV of the "Publications of the Lick Observatory, 1900."

3. Meteorology.—To make quite sure of the condition of the atmosphere at any time during the observations, the thermometers were read, on the average, three times an hour (at nearly equal intervals); and the barometer was observed every hour. The reading of the wet bulb thermometer was also taken when the dry was read. The relative humidity has not been introduced into the reductions, but it was thought desirable to have it for possible future reductions.

The barometer, Green 2839, hangs on the north wall of the observing room. It reads to one two-hundredth of an inch. The dry and the wet bulb thermometers (F) hang in the air space between the north walls. The dry bulb thermometer, used to indicate the external temperatures, is Green 494. This thermometer has been calibrated at the Yale Observatory. The corrections which have been applied to all the readings have been taken from the following table sent from Yale Observatory:—

<i>t</i> (F)	Cor.
o°	+o°.1
32	-0 .2
52	т. о—
72	-0.2
112	1. 0—

The table which follows contains the *uncorrected* temperatures (t), the readings of the attached thermometer (T), of the barometer (B), and the times at which they were taken. The readings of the wet bulb thermometer are not given here.

Nors.—On the nights of June 7, 8, 9, 12, 13, 14, 19 and 22 some of the observations were made at times a little different from those given in the column 5td. T. The actual times of such observations are indicated just before the column t. Thus, on June 7 before the column t cocur the numbers 0, 7, and 8, which indicate that the times of the corresponding observations were 160 instead of 15.9, as given in the column 5td. T., 167 instead of 16.5, 178 instead of 17.7; etc.

In this table the unit of B is one two-hundredth of an inch.

From this table the following data have been taken:

```
Maximum temperature = 74°.0, July 3

Minimum temperature = 55°.1, June 12

Maximum range = 18°.9

Maximum barometer = 5194, June 14

Minimum barometer = 5145, June 12

Maximum range = 49.
```

During this period of observing, the maximum difference between the dry and the wet bulb thermometers was $75^{\circ}.5 - 48^{\circ}.0 = 22^{\circ}.5$. This was on June 29. The minimum was $65^{\circ}.0 - 56^{\circ}.0 = 9^{\circ}.0$, which occurred June 27.

Concerning the maximum temperature noted above, 74°.0, it should be remarked that this was the first reading of the period, and was taken several minutes before the sun had set.

Besides the regular thermometers in the air space between the north walls, three other thermometers were suspended from the ceiling of the observing room. All three were swung under the observing slit, near the plane of the meridian. One was directly over the instrument, and three or four feet from the ceiling. The other two were hung, one north and one south, about half way between the instrument and the north and south walls respectively, and at such a distance above the floor that the plane of the axis of the instrument and the line of sight of the telescope, pointed at about 83° zenith distance (north and south respectively), would intersect the thermometers near their bulbs.

Before being thus placed, these thermometers were compared with Green 494, so that their readings could be reduced for comparison with those of the external thermometer (Green 494).

During the course of an evening's observations these three thermometers were read just after reading the regular thermometer. The average difference between the inside and the outside thermometers was found to be the same for all three, and is o°.3 (F). It is nearly always the case (in this hemisphere) that the southern part of a room is a trifle warmer than the northern. But this is not the case on Mount Hamilton. The temperature of the air inside is, on the average, very uniform and but very little (o°.3) warmer than the air outside. In his "Untersuchung über die Astronomische Refraction u. s. w.," Dr. Bauschinger notes that the southern part of his observing room in Munich was warmer than the northern, and that at night the average difference between the inside and the outside temperatures is 1°.3 (C). From his investigation, he concludes that the temperature of the air within the observing room should be taken into account.

Because of these difficulties, many observers have seriously considered the idea of mounting their instruments under a movable house, so that when at work the instrument will be entirely out of doors, and thus completely obviate this difficulty. But this would needlessly endanger the instrument. To accomplish the same purpose, the Meridian Circle house being built at Kiel is to be constructed in the shape of a cylinder whose axis coı̈ncides with the axis of the instrument. This is undoubtedly the best form of construction.

For the efficiency of the Meridian Circle house on Mount Hamilton, the difference between the inside and the outside thermometers can speak. As has been said, the average difference (in the sense Inside-Outside) is + 0°.3 (F). The maximum difference noted was one evening, a few minutes before the sun had set, when the difference was + 1°.1 (F). The maximum difference noted here is less than half the average at Munich. After this Meridian Circle house has been completely opened for an hour and a half, the temperature inside is practically the same as it is outside.

During the months October to December, inclusive, a similar set of observations was secured. For these months the average difference between the inside and the outside temperatures is even less than for the summer months. But the range of the difference is much greater for the

fall and the winter months. The maximum differences observed were — 2°.0 (F) and + 2°.1 (F). There was one still larger difference, viz. — 3°.7 (F), which can hardly be counted in the series, for it occurred on a poor night, immediately after observing had been suspended because of clouds and poor "seeing." The hot wave, which caused the outside temperature to rise suddenly, undoubtedly destroyed the "seeing." Although the winter months present conditions not so favorable as those of the summer months, nevertheless they also speak well for the efficiency of the Lick Observatory Meridian Circle house.

4. Plan for Observing.—The method of determining the refractions here may be stated as being a quasi converse to Talcott's method of determining the latitude. Instead of eliminating the refractions to get the latitude, the method is to determine the refractions by eliminating the latitude, as follows:

Let

z. = the zenith distance of a southern star,

 z_n = the zenith distance of a northern star,

 z'_s = the apparent zenith distance of the southern star,

 z'_n = the apparent zenith distance of the northern star,

 δ_{\bullet} = the declination of the southern star,

 δ_n = the declination of the northern star,

r_s = the refraction of the southern star,

 r_n = the refraction of the northern star,

 φ = the latitude of the Meridian Circle.

Then

$$\delta_{n} = \varphi + z_{n} = \varphi + (z'_{n} + r_{n}) \tag{1}$$

$$\delta_{s} = \varphi - z_{s} = \varphi - (z'_{s} + r_{s}) \tag{2}$$

$$\delta_{n} - \delta_{s} = z'_{s} + z'_{n} + r_{s} + r_{n}$$
(3)

Let

$$A = \delta_n - \delta_s \tag{4}$$

$$B = z'_n + z'_n \tag{5}$$

Then

$$A = B + r_s + r_n \tag{6}$$

or

$$\mathbf{r_s} + \mathbf{r_n} = \mathbf{A} - \mathbf{B} \tag{7}$$

If now, the southern and northern zenith distances were the same, and if, at the times of observing them, the conditions of the atmosphere were the same, the two refractions would be the same, i. e.,

In this case we have
$$\begin{array}{c} r_s = r_n. \\ 2r = A - B \end{array}$$
 (I)

In practice these ideal conditions are only approximately We therefore proceed as follows: satisfied.

From (7) we have
$$2r_a-r_a+r_n=A-B \qquad (8)$$

whence

$$2r_a = (A - B) + (r_a - r_n)$$

and

also
$$r_{s} = \frac{1}{2}(A - B) + \frac{1}{2}(r_{s} - r_{n})$$

$$r_{n} = \frac{1}{2}(A - B) + \frac{1}{2}(r_{n} - r_{s})$$
(II)

In case the northern star is at lower culmination we shall have:

$$\delta_{n} = 180^{\circ} - z_{n} - \varphi \tag{9}$$

$$\delta_s = \varphi - z_s$$
 (10)

$$\delta_{n} + \delta_{s} = 180^{\circ} - z_{n} - z_{s} \tag{11}$$

$$= 180^{\circ} - [z'_{n} + r_{n} + z'_{s} + r_{s}]. \tag{12}$$

$$=180^{\circ} - [z'_{n} + r_{n} + z'_{s} + r_{s}]. \tag{12}$$

Hence

$$r_n + r_s = 180^{\circ} - [z'_n + z'_s] - [\delta_n + \delta_s]$$
 (13)

and

$$2r_s = 180^{\circ} - [z'_n + z'_s] - [\delta_n + \delta_s] + [r_s - r_n].$$
 (14)

Calling

$$A' = \delta_n + \delta_a \tag{15}$$

and since

$$B = z'_{n} + z'_{n} \tag{5}$$

we have

and

$$r_{s}=90^{\circ}-\frac{1}{2}[A'+B]+\frac{1}{2}[r_{s}-r_{n}]$$

$$r_{n}=90^{\circ}-\frac{1}{2}[A'+B]+\frac{1}{2}[r_{n}-r_{s}]$$
(III)

In order to obtain the refractions from (II) and (III) it is necessary to know the declinations of the stars, their apparent zenith distances (or rather the sums of the zenith distances of the pairs of north and south stars), and the differences between the refractions of the pairs. stars chosen for this work are all fundamental, and in a first approximation their declinations are to be considered absolute. The list of stars, given later, has been taken from Professor Newcomb's "Catalogue of Fundamental Stars for 1875 and 1900, reduced to an absolute System." The apparent zenith distances, or the sums of the zenith distances of the several pairs, are obtained from the Meridian Circle observations; and the differences in the refractions are found by computing the refractions from some standard table. In this work the Pulkowa tables have been used. The term $\frac{1}{2}(r_s-r_n)$ being of the nature of a differential refraction, any error in the constant of refraction of the table used will have practically no effect upon this difference. The more nearly ideal conditions (i. e., when $r_s=r_n$) are approached, of course, the better the determination of the refractions will be.

This method has both its advantages and its disadvantages. Among the former, the most important are: first, the total elimination of the latitude and hence also of its variation; second, the elimination of the nadir, since $(z'_n+z'_n)$ is nothing more nor less than the difference between the circle readings, and is therefore independent of the zenith point; third, there is no wait of twelve hours or of six months in order to observe a star at both culminations, as is usually done; and fourth, the simplicity of the reductions.

The greatest disadvantage in this method lies in the fact that the declinations of the stars have to be considered known. But by taking fundamental stars, such as those whose places are given by Professor Newcomb's new Fundamental Catalogue, and by taking a large number of these stars, this difficulty will be nearly completely eliminated.

Having now the new refractions, the correction to the constant of the table used (Pulkowa) is found from the following equation [eq. (701) pg. 672, Vol. I, Chauvenet, "Spherical and Practical Astronomy":

$$dr = Ada + Bd\beta,$$

$$A = \frac{r}{a}$$

$$B = \sin^2 z \sqrt{\frac{2}{\beta}} \left(\frac{dQ}{d\beta} - \frac{Q}{2\beta} \right).$$

and

where

For this observatory, whose altitude is 4,209 feet and where the mean annual pressure is less than 26 inches, an investigation into the effect of the higher powers of $\triangle \beta$ involved in the factor $\beta = \frac{b}{R} = I + \frac{b - B}{R} = I + \frac{\triangle b}{R}$ (in Bessel's notation for r) was necessary. In his memoir, "Untersuchungen über die Constitution der Atmosphäre und die Strahlenbrechung in Derselben," St. Petersburg, 1866, Gyldén has neglected the squares and higher powers of $\frac{\triangle b}{B}$, since for places at low altitudes $\frac{\triangle b}{B}$ is a very small quantity. This investigation was made by Professor Comstock (Vol. I, "Publications of the Lick Observatory"). From his investigation the conclusion is drawn that "the Pulkowa Refraction Tables may be used for atmospheric pressures as low as 25 inches without taking into account the squares and higher powers of $\wedge b$, and the quantities so neglected will not be sensible at zenith distances less than 80°." The minimum reading of the barometer during these observations was 25.72 inches, so that in these reductions no modification of the factor of the refraction depending upon the barometer need be made.

This question having been disposed of, the assumption is here made that all of the error in the refractions is due to an error in the constant of refraction. This amounts to assuming the constant β to be correct or that $d\beta$ =0. The equation above then reduces to the very simple expression

$$dr = Ada = \frac{r}{a} da;$$

hence

$$\frac{\mathrm{d}a}{a}=\frac{\mathrm{d}r}{r},$$

or

dloga=dlogr.

Having dlogr from the reductions, we thus have dloga, and hence da.

This assumption would perhaps seem somewhat risky for stars whose zenith distances are greater than 80°. But at the conclusion of the reductions, the value of dloga deduced

from such stars was found to fit in very well with those deduced from the other stars. Furthermore, down to 85° zenith distance the observing was very good. In consequence of these facts it was decided to take into account all the stars observed. The zenith distances of the stars in this list range from 21° 21' to 89° 12' (apparent).

From 85° zenith distance down, the quality of the "seeing" decreases quite rapidly. This can be seen from the following table of average weights. These weights were derived from the probable errors of the individual determinations of dloga.

Z . D .	Av. Wt.
20° to 30°	2.0
50 to 60	7.5
60 to 70	7.5
70 to 80	11.8
80 to 85	14.8
8s to 90	3.6

The small weight for the small zenith distances is due to the fact that in the expression for da the refraction occurs in the denominator. The small weight for the stars at zenith distances greater than 85° is, of course, due to uncertainties in observing at such low altitudes.

OBSERVATIONS.

1. List.—The following list of 31 stars was observed on seventeen nights, from 1899 June 7 to 1899 July 6, inclusive, and have been reduced according to the plan outlined in the preceding section. Eleven other stars were on the same observing list, but they have not been used here. They were put on to obtain data for determining bisection error, and for other purposes.

The numbers of the stars are those of Newcomb's "Catalogue of Fundamental Stars for 1875 and 1900, reduced to an Absolute System."

2. Details of Observations.—A night's program consisted in observing the above list, together with three nadirs, one before, one during, and one after the observing of the stars. As has been pointed out, the nadirs are not necessary for the refraction determinations, but were taken for the reduction of the latitude, which is a problem practically inseparable from the main one undertaken here.

No transits were observed during these observations, the whole attention being devoted to the observations for zenith distance. The telescope was set to the nearest 2' and not disturbed until the observation had been completed. The bisection was made (with but a very few exceptions) at the central transit wire, by means of the declination micrometer. For the sake of uniformity every star was bisected but once during its transit. Because of unavoidable circumstances a few of the stars had passed the meridian before the bisection

could have been made. In these cases the readings have been reduced to the meridian.

For the position of the circle four microscopes were read. Settings were made upon two scratches under every microscope. The circle microscopes were usually read after the star had been bisected. In a few cases, because of a following star culminating very soon, the microscopes were read before the bisection. In such cases the position of the circle was quickly checked after the bisection.

The correction for runs for a night was obtained from all of the microscope readings of the night. This correction has been applied to all of the observations. Its values for the several nights of observing are given in the following table:—

Date	R	Date	R	Date	R
June 7	+0".06	June 19	+0".02	June 30	+o".o6
8	+o.o8	21	+0 .03	July 3	+0.07
9	+0.08	22	+0.03	4	+o .o8
12	+0.05	27	+0.04	5	+0 .05
13	+0 .03	28	+0 .07	6	+∘ .08
14	+0 .07	29	+0.06		

These corrections were applied to the circle readings to reduce them to the mean position of the two scratches; so that for a reading of o" the correction is +R, for 60" it is 0, and for 120" it is -R.

In the few cases where the bisections were made a little late the reductions to the meridian were computed from the formula.

$$\delta = \delta' - \frac{\sin^2 \frac{1}{2} (\tau - m)}{\sin \tau''} \sin 2\delta'$$

The horizontal flexure in this instrument is very small. In his work published in Vol. IV, "Publications of the Lick Observatory," Astronomer Tucker adopts the correction o". 1sin Z. D., which was determined from a series of observations extending over two and a half years. In this work but two observations for flexure were made, one on 1899 June 3, and the other, 1899 July 8. The mean of

the two gives the correction —o".o1sin Z. D.; so that for these observations the flexure correction has been considered zero. The mean of the values of one revolution of the declination micrometer, determined at the same time, is 48".05. The value adopted, as noted before, is 48".10.

For the computation of the preliminary-refractions (called r' in the reductions) the Pulkowa tables have been used. The reductions for the barometer, for the attached, and for the external thermometers were taken from Vol. I, "Publications of the Lick Observatory."

The graduation errors of the 1° divisions of the fixed circle have been determined by Astronomer Tucker. His results are given in Vol. IV, "Publications of the Lick Observatory." He says there, in part: "The probable error of a reading upon four divisions of the fixed circle due to graduation may be adopted as ±0".15. * * * There is some evidence of periodic character in the errors, and it may be assumed, in absence of further data, that the probable error due to errors of graduation is not diminished by reading upon two adjoining divisions under each microscope. * * The largest error measured is 0".7 for the mean of four divisions."

The errors are not sufficiently systematic to warrant interpolating for undetermined divisions, so that no correction for division error has been applied.

Three nadirs were observed every night. The changes during a night were usually very small. The following table gives the means of the three determinations on the several nights:

Date	Nadir 134° 57′	t	Date	Nadir 134° 57′	t
June 7	22".87	62°	June 27	20".95	66
8	22 . 18	66	28	21 .32	67
9	22 . 14	69	29	21 .40	69
12	24 .41	57	30	21 .70	66
13	22 .70	62	July 3	21 .43	72
14	21 .61	70	4	21 .46	69
19	23 .81	57	5	22 .91	61
21	22 .36	66	6	22 .10	58
22	21 .59	67	ll .		

All of the observations were taken with the fixed circle west. Had more time been available the instrument would have been reversed.

Weights, ranging from 5, the highest, to I (occasionally ½), the lowest, were arbitrarily assigned to all the observations. Judgment on a weight was formed from the steadiness of the image during the observation. These weights have been applied all through the reductions.

3. Reduction of Observations.— The first thing done on the reductions was to take the means of the microscope readings and to apply the micrometer corrections, giving the circle readings (called C' in the tables following). The means of the microscopes were checked by taking the difference of every microscope reading from the mean of the four. If the sums of these differences for the two opposite pairs of microscopes was the same, the mean was correct. The corrections for the micrometers were checked by duplicating this part of the work.

From the readings C' the quantity B [equations (II) and (III)] is obtained. The terms A and A' of these equations are obtained from the declinations.

The declinations have been reduced to 1899.0 by means of the data furnished in Newcomb's Catalogue. The reductions to apparent places were computed by using the Besselian Star Numbers from the American Ephemeris. The factors a', b', c' and d' were computed from the American Ephemeris data. The reductions to apparent places for the first night (June 7) were computed by means of the Independent Star Numbers also. The places for the remaining nights were checked by differences. The apparent declinations are placed in the columns δ of the tables given later.

The following table exhibits the stars' approximate zenith distances and the stars with which they are grouped in the reductions for the refractions:

It will be noticed from this table that some of the stars are grouped with two others and that one is grouped with three others.

The following tables show the reductions for the new refractions. The column p contains the means of the weights of the pairs of stars. The other columns have already been explained. In the grouping of the pairs on the several dates the northern star is written first and the southern star below it. The numbers of the stars given at the tops are arranged in this same order. The pairs which have their northern stars at upper culmination are placed first. It will be noticed that the headings of the columns for these pairs are slightly different from the later ones containing the lower culmination stars.

Because of very bad "seeing" or of occasional accidents, some of the stars were not observed on some nights. In such cases blanks appear after the dates. No observations have been rejected.

STARS No.  $\left\{\begin{array}{l} 438 \ l. \ c. \end{array}\right\}$  (Com.)

The following tables contain the reductions for dlogr or its equivalent dloga. The second column contains the logarithms of the computed refractions; the next column contains the logarithms of the observed refractions; the fourth the difference between the two preceding, in the sense of Observed—Computed; the column p contains the weights and the last column the weighted differences. The residuals and their weighted squares are not given. Log [pvv] is given in every case, as is also the resulting probable error of the weighted mean of every set. All of the results in the following tables have been checked.

STAR No. 948.

[ / ] = 340.6

[pvv] = 0.00108489 $\triangle = -0.00180 \pm 0.00019$  4. The Constant of Refraction.—The value of a deduced by Gyldén for the Pulkowa Tables, as given in his "Untersuchungen über die Constitution der Atmosphäre u.s.w.," is

$$a = 0.00027985 = 57''.723$$
.  
This is for  $B = 29.5966$  inches at  $0^{\circ}$  and  $t = 7^{\circ}.44$   $R$ .

The Pulkowa Tables used here, however, are Gyldén's with  $\mu$  systematically reduced by — 0.00124. Combining this with the value found for  $\triangle a$ , the correction to Gyldén's constant becomes

$$\triangle a = -0.00304a$$
  
= -0".175  
 $a = 57".548$ .

and

This reduced to the condition of 760 mm. pressure at oo and oo C temperature gives

$$a = 60^{\circ}.159.$$

To this value of a correspond the following:

$$c = 0.00029182$$
  
 $\mu = 1.00029178$ .

and

For the sake of comparison, the most important determinations of the constant of refraction are given below. These values are for the conditions B=760 mm. at  $0^{\circ}$  C and external thermometer =  $0^{\circ}$  C. (These values are taken from Professor Bauschinger's "Untersuchungen über die Astronomische Refraction u.s.w.").

		a	$\mu$
I.	Fund. Astr	60".320	1.00029257
2.	Tab. Reg	.440	29315
3.	Tab. Pulk	.268	29232
4.	Fuss	.122	29161
5.	Greenw. 1857-1865	.120	29160
6.	Pulk. 1865	.209	29203
7.	Greenw. 1877-1886	.192	29195
8.	Pulk. 1885	.058	29130
9.	München	.104	29152

The first and second of these are determinations by Bessel; the third by Gyldén; the fifth by Stone; the sixth by Nyrén; the seventh by Newcomb; the eighth by Nyrén; and the last by Bauschinger.

Bauschinger gives weight zero to each of Bessel's determinations; to the first, because there was considerable uncertainty in Bradley's meteorological instruments; to the second, because of the uncertainty in reading the Meridian Circle (read by vernier to one second). He gives equal weight to the last seven, and gets for a mean

$$a = 60^{\circ}.153$$
 and  $\mu = 1.00029176$ .

5. Latitude.—The following table gives the value of  $\varphi$  deduced separately from the southern and from the northern stars. All of the stars of the list down to 84° Z. D. were used.

Date	$\varphi_{\mathrm{s}}$	p	pφs	$\varphi_{_{\mathrm{N}}}$	ø	$p \varphi_{N}$

	Σ	73	1893.25		61	1513.31
Weighted	d mean 🛭		25.93	ł		24.81

Applying the new refractions found here, the latitudes become from the

Southern Stars —  $\varphi = 25^{\circ}.55$ Northern Stars —  $\varphi = 25$ .19 giving for the mean  $\varphi$  at this epoch (1899 June 22),

$$\varphi = + 37^{\circ} 20' 25''.37.$$

The remainder of the difference between the values of  $\varphi$  as found from the northern stars and from the southern stars (0".36) is probably due to slight errors in the declinations of the stars used, and to bisection error.

#### Conclusion.

In conclusion it is desired to state that limitations of time have prevented the *complete* reduction of these observations and of the series taken during the fall months (1899 Oct.—Dec.). It is hoped that, in the near future, time will be available in which to carry out these reductions by correcting the declinations used and then repeating such portions of these computations as will be necessary. It is also desired to make reductions which will include the relative humidity and a term depending upon the zenith distance.

It will be noticed from the table (p. 189) that there is a large range in the values of  $\triangle$ , viz., from — 0.00584 to + 0.00662. This discordance is due partly to the values of the declinations adopted, but is also very clearly a function of the zenith distance. By introducing a term depending upon the zenith distance, and re-solving by Least Squares, this discordance can be greatly diminished.

From this investigation the following conclusions can be drawn:—

1. That this preliminary reduction gives for the Constant of Refraction

$$a = 60''.159$$
 for  $B = 760$  mm, at  $0^{\circ}$  (C) and  $t = 0^{\circ}$  (C).

2. That for the epoch 1899 June 22, the latitude of the Lick Observatory Meridian Circle was

$$\varphi = +37^{\circ} 20' 25''.37.$$

- 3. That the final reduction will show that the Constant of Refraction of the Pulkowa Tables is too large.
- 4. That the observing room of the Lick Observatory Meridian Circle is of a very good design, and that there is no need of mounting Meridian Circles in the open air.

#### ADDENDUM.

The table on page 189 shows a large range in the values of  $\triangle$ , viz., from +0.00662 to -0.00584. Upon plotting these values, using the zenith distance z for abscissa, and  $\triangle$  for ordinate, it is easily seen that  $\triangle$  varies quite uniformally with the zenith distance. A straight line, inclined about 145° to the zenith distance axis, and cutting it at z= about 55°, appears to represent  $\triangle$  very well. Therefore, assuming Z to be the zenith distance for  $\triangle=$  0, we can set up an observation equation of the following type for every star:

$$\log a = \log a_0 + [Z-z]x$$
,

or

$$\log a = \log a_o = \Delta = Zx = Zx = D = zx$$
,

where

$$D=Zx$$
.

and where  $a_0$  is the a of the tables used (Pulkowa).

Equations of this kind were, accordingly, formed and solved for Z and x by the method of Least Squares.

Equations of Condition.

$$\triangle = D - zx$$
.

11		_	65.34	= +	41	18.4	4.3	

## Weighted Observation Equations.

No.	a		ь	n		
1	8.6 D		681.1 x	= -0.6	01496	
2	3.2	_	284 . 1	= -	1552	
3	2. I		57.9	= +	1248	
4	2.7	_	58.o	= +	1040	
4 5 6	5.4	-	309.5	= -	632	
6	5.2	_	452.4	= -	1664	
7 8	2.2	_	59 · 7	= -	227	
8	5.0	_	313.7	= -	35	
9	4.2	_	282.9	= -	35 353 3230	
10	II.I	_	926.7	= -	3230	
11	4.3	_	281.O	= +	176	

To render these more nearly homogeneous, let D=D; 100x=y and multiply the absolute term by 100. Then we have the following

## Weighted Homogeneous Observation Equations.

No.	a		b	n			
1	8.6 D	_	6.811	y	=	_	1.496
2	3.2	_	2.841	•	=	_	1.552
3	2. I	-	0.579		=	+	1.248
4	2.7	_	0.580		=	+	1.040
5 6	5.4	_	3.095		=	_	0.632
6	5.2	-	4.524		=	_	1.664
7 8	2.2	_	0.597		=	_	0.227
8	5.0	_	3.137		=	_	0.035
9	4.2	_	2.829		=	_	0.353
10	II.I	_	9.267		=	_	3.230
11	4 3	_	2.810		=	+	0.176

Combining these by the method of Least Squares we obtain the following

# Normal Equations.

$$+341.28 D$$
— $254.512 y$ =  $-61.7188$   
 $-254.51 + 197.151 = +53.4383$ 

Solving these, remembering that the absolute terms had been multiplied by 100, we have

$$\log D=7.75694$$
;  $\log y=8.00376$  or  $\log x=6.00376$ .

Now since D=
$$Zx$$
, we have log Z=1.75318,  
Whence  $x=+0.0001009$  and  $Z=56^{\circ}.647=56^{\circ}38'49''$ .

Substituting the values of D and x, thus found, in the Weighted Observation Equations, we find [pvv] =

0.00024690, from which the following probable errors have been deduced:

$$r_x = \pm 0.0000130$$
 and  $r_Z = \pm 0^{\circ}.031 = \pm 0^{\circ}1'52''$ .

We, therefore, have from this solution

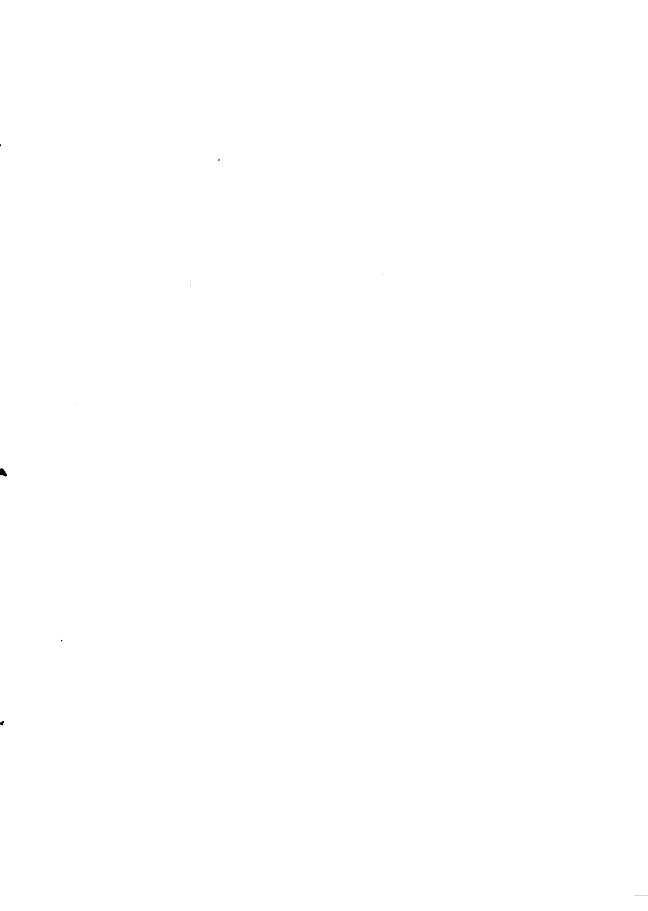

$$Z=56^{\circ}38'.8\pm1'.9$$
 and  $x=+0.000101\pm0.000013$ , giving

 $\log a = \log a_0 + 0.000101 [56^{\circ}38'.8-z].$ 

We are, therefore, led to the conclusion that the so-called Constant of Refraction needs not only a correction, but a correction for every zenith distance. In other words, the formula from which refractions are computed needs to be modified. Or, the formula may be retained unaltered, and the desired result obtained by correcting the log  $\mu$  table of the refraction tables used (Pulkowa) by the amount

$$\triangle \log \mu = 0.000101 [56^{\circ}38'.8-z].$$
